NORTHERN CALIFORNIA

The Permanente Medical Group, a growing multispecialty group, is recruiting for positions in our beautiful Northern California region: the San Francisco Bay Area, Sacramento and the Central Valley.

REPRODUCTIVE ENDOCRINOLOGIST

• SAN JOSE •

We are currently seeking a Reproductive Endocrinologist to establish and run a reproductive endocrinology subdivision in the department. Duties would include the full spectrum of reproductive endocrinology, outpatient and surgical management of infertility. Fellowship certification would be preferred. The department currently has 17 physicians and is still growing. We offer a generous benefits package including full coverage malpractice insurance. San Jose has beautiful weather and excellent access to Bay Area recreational and cultural activities.

For more information, please contact: Jerome L. Nehemiah, M.D., Chief, Department of OB/GYN, The Permanente Medical Group, Inc., 260 International Circle, Dept. AJOBG, San Jose, CA 95119, or call collect (408) 972-6180. EOE

KAISER PERMANENTE
Good People. Good Medicine.

CHAIRPERSON, DEPARTMENT OF OBSTETRICS AND GYNECOLOGY, MEHARRY MEDICAL COLLEGE

The School of Medicine of Meharry Medical College invites applications from and nominations of candidates for the position of Professor and Chairman of its Department of Obstetrics and Gynecology. Affiliated institutions include Metropolitan General Hospital in Nashville, TN, and Blanchard Army Hospital in Ft. Campbell, KY. Chair responsibilities include the continuing development of the Department, direct patient care, teaching and research. The candidate must be board certified, have a record of scholarly contributions to the literature and participation in professional organizations and possess strong leadership qualities. An administrative background would be desirable. Nominations or applications should include a curriculum vitae and three references. Please forward no later than July 1, 19890 to:

Harold D. Thompson, M.D.
Chairman, Search Committee for
Obstetrics and Gynecology
Meharry Medical College
1005 D.B. Todd Blvd.
Nashville, Tennessee 37208

UCLA INTERCAMPUS MEDICAL GENETICS TRAINING PROGRAM

The UCLA intercampus post-doctoral research training program in Medical Genetics utilizes the research and clinical resources of its affiliated campuses an teaching hospitals. The program is open to academically oriented applicants with the M.D., Ph.D., D.D.S. or equivalent degrees. A wide variety of research training opportunities in molecular, biochemical, immuno-, cancer, cyto-, somatic cell, population and clinical genetics are available. The program also meets all the requirements of the American Board of Medical Genetics. Clinical genetics fellowships are available at each of the affiliated hospitals. Application forms are available from David Minoin, M.D., Ph.D., Department of Pediatrics, Cedars-Sinai Medical Center, 8700 Beverly Blvd., Los Angeles, CA 90048.

Postdoctoral Training Program in Medical Genetics

The Interdepartmental Medical Genetics Program at Stanford University School of Medicine provides advanced clinical and/or research training related to human inherited disease. Well-represented areas of the program include:

- The molecular basis of heritable disorders including polygenic and multifactorial diseases.
- Chromosome structure and function.
- Genome and gene mapping.
- The development of methods to manipulate and to study large fragments of DNA.
- Developing animal models and new treatment modalities of human genetic disease by homologous recombination.

Individuals with an MD, PhD, or equivalent degree are eligible for this three-year program which includes an extended period of research training with one of twenty-six training faculty and the opportunity to pursue applied training in clinical genetics, clinical cytogenetics, or molecular genetics in an ABMG-accredited setting. Minority individuals are especially encouraged to apply. For information and application forms, contact:

Uta Francke, M.D.
Departments of Genetics and Pediatrics
Howard Hughes Medical Institute
Stanford, California 94305-5428

FACULTY POSITIONS CALIFORNIA

International Medical Course

Modern obstetric care

14-22 November 1990, London

Clinical obstetrics is changing rapidly, in response to the many scientific advances of the last decade. This course reviews modern techniques and their applications. In all cases, the clinical applications will be stressed and participants will be welcome to make contributions of their own work in the field of foetal medicine or perinatal obstetrics. The following areas will be covered in the course: basic genetics and its influence in clinical medicine; the events around implantation; foetal and neonatal growth; recurrent abortion; multiple pregnancy, congenital abnormalities; labour.

The course will be directed by **Professor Geoffrey Chamberlain** and **Mr Malcolm Pearce** of the Department of Obstetrics and Gynaecology, St George's Hospital Medical School, University of London.

The course is aimed at consultants and specialists in obstetrics and gynaecology. It is essentially a clinical course with a scientific background; most of the speakers are in charge of the clinical practice of modern obstetric care, but have performed basic research in their own clinical area.

There are vacancies for 30 participants.

Course fee: £805; accommodation charge: £535; total fee: £1340.

The working sessions will be held at St George's Hospital Medical School. Resident participants will be accommodated at a hotel in rooms with private bath or shower.

The British Council

Further information and application forms are available from British Council Representatives overseas or from Courses Department, The British Council, 65 Davies Street, London W1Y 2AA.

THERAPEUTIC HYSTEROSCOPY: Indications and Techniques

Edited by **Alvin M. Siegler**, M.D.; **Rafael F. Valle**,M.D.; **Hans J. Lindemann**, M.D.; and **Luca Mencaglia**, M.D.

Edited by a team of international experts on hysteroscopy, this new book promises to help make this endoscopic technique a part of every gynecologist's practice. Emphasizing technique with much improved instrumentation, it provides the step-by-step instruction you need to know to treat intrauterine disorders. The authors assume the reader is already very familiar -- if not proficient -- with the hysteroscope as a diagnostic tool, and focus instead on operative therapeutic techniques. It reviews instruments and indications for each condition, and presents "how-to" information for each procedure. Extensive illustrations -- many in full color complement the text.

March, 1990. Approx. 224 pages, 360 ills. **(Book Code: 05504)**

Let our eminent medical authorities guide you through major new clinical advances

Introducing the

Year Book of Obstetrics & Gynecology®

This time-saving guide book makes it easy for you to keep current in your field. Each volume represents the year's most significant developments as reported in more than 800 journals and periodicals published worldwide. These selections are condensed to roughly a page in length, so you get all essential facts at a glance.

More importantly, the distinguished physician editors provide thoughtful, probing commentaries that explore the significance of each article while evaluating its practical implications for day-to-day practice.

Editors: Daniel R. Mishell, Jr., M.D.; Thomas H. Kirschbaum, M.D.; and C. Paul Morrow, M.D.
Contributing Editor: William H. Hindle, M.D.

These books are published annually. For the convenience of its customers, Year Book enters each purchaser as a subscriber to future volumes and sends annual announcements of each volume approximately two months before publication. The new volume will be shipped upon publication unless you complete and return the cancellation notice attached to the announcement and it is received by Year Book within the time indicated (approximately 20 days after your receipt of the announcement). You may cancel your subscription at any time. The new volume may be examined on approval for 30 days and returned for full credit. Year Book will remove your name as a subscriber. Return postage is guaranteed by Year Book to the Postal Service.

To Subscribe:

Simply fill out this coupon and send it to us at the address shown.

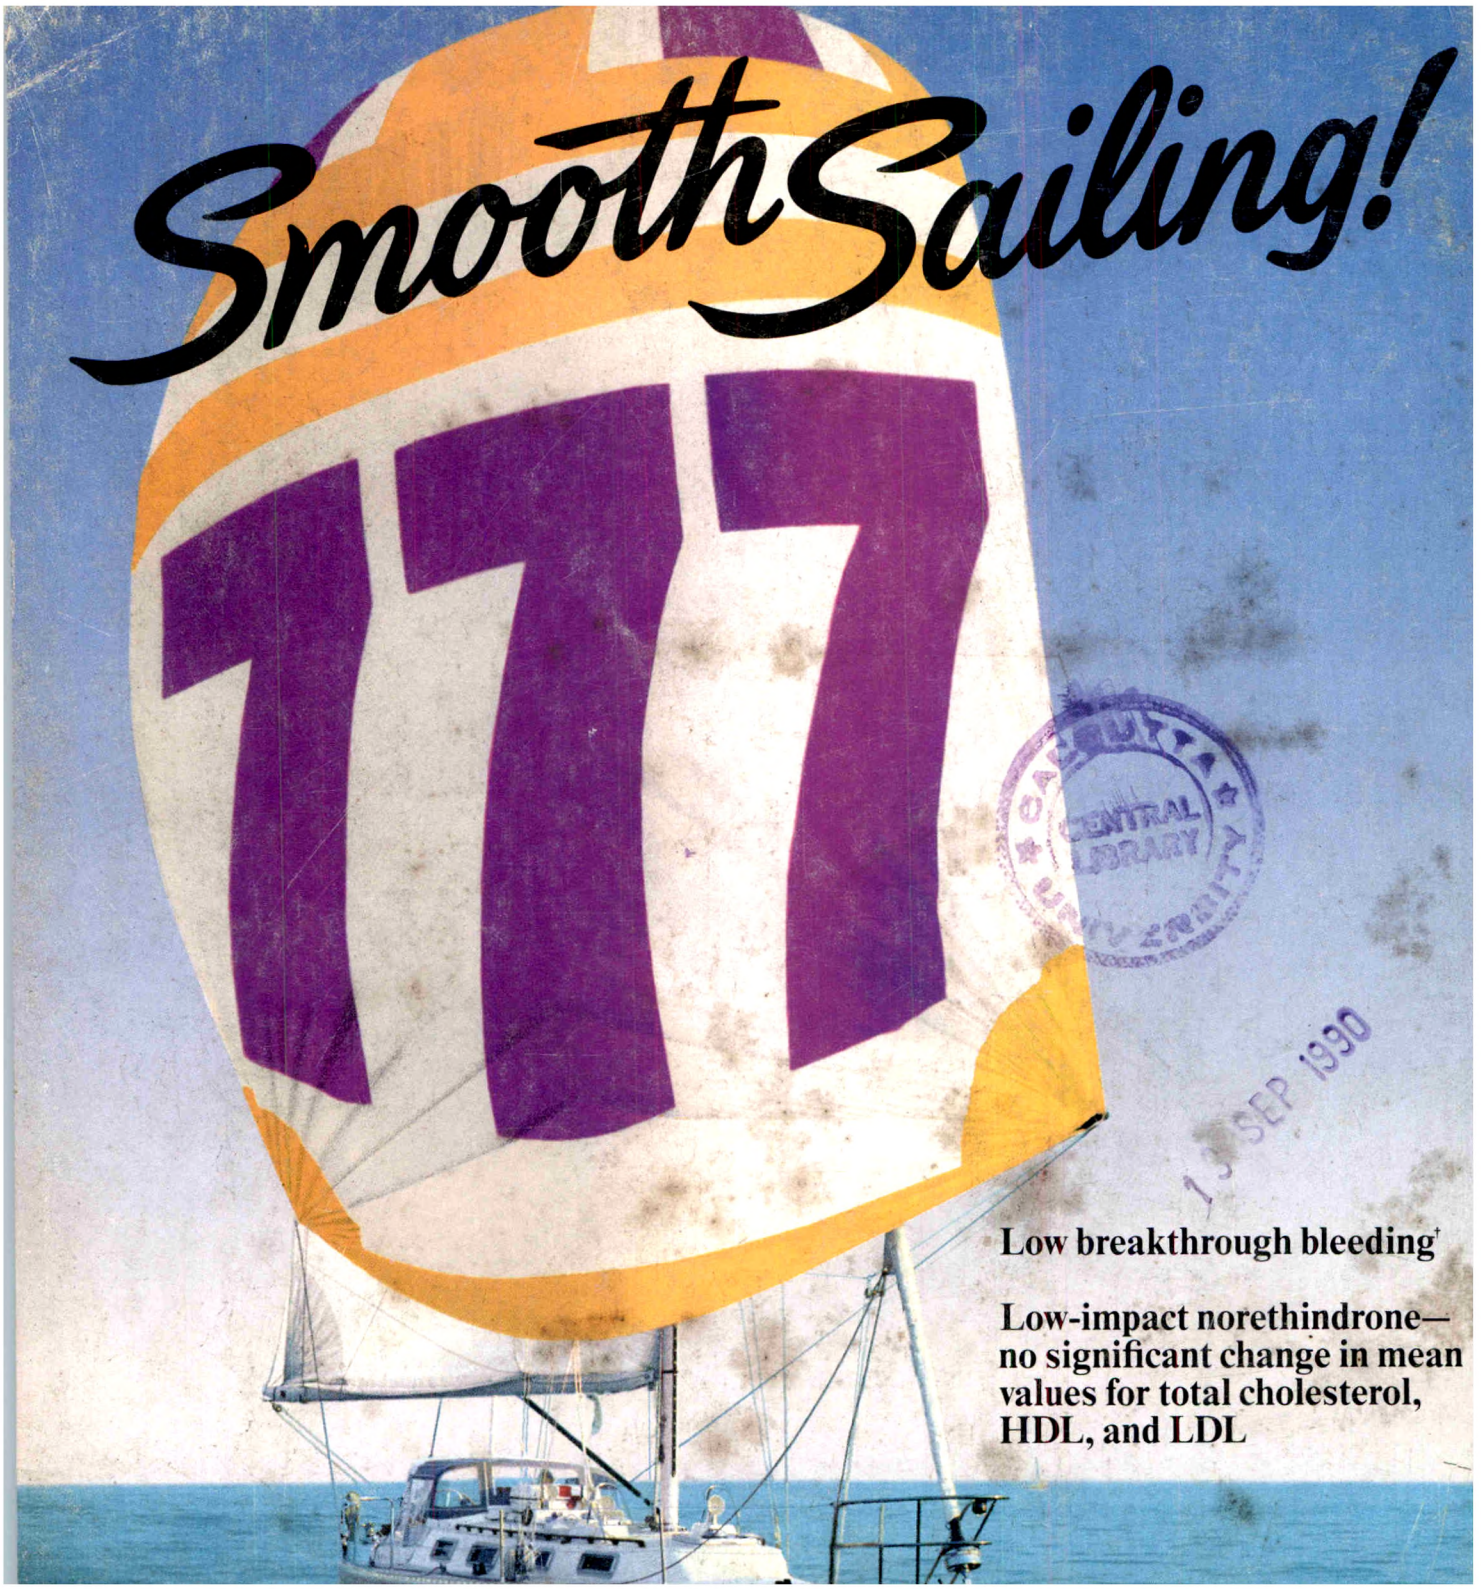
Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28 day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

CONTRAINDICATIONS: Oral contraceptives should not be used in women who currently have the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Carcinoma of the endometrium or other known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice with prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

WARNINGS



Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, and gallbladder disease, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this brief summary is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this brief summary epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease, namely a *ratio* of the incidence of a disease among oral contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods. 1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. a. Myocardial Infarction. An increased risk of myocardial infarction has been associated with oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers, especially in those 35 years of age and older among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in WARNINGS). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors. b. Thromboembolism. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease associated with oral contraceptives is not related to length of use and disappears after pill use is stopped. A two- to four-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate postpartum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four weeks after delivery in women who elect not to breast feed. c. Cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users, for both types of strokes, and smoking interacted to increase the risk of stroke. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for nonsmokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women. d. Dose-related risk of vascular disease from oral contraceptives. A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the activity of the progestogen used in the contraceptive. The activity and amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing 0.035 mg or less of estrogen. e. Persistence of risk of vascular disease. There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral contraceptive formulations containing 50 micrograms or higher of estrogens. 2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE. One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who use oral contraceptives have a significant increase in mortality higher than those using other methods of birth control. These facts must be weighed in conjunction with failure rates for other methods and the risk associated with subsequent pregnancy. 3. CARCINOMA OF THE REPRODUCTIVE ORGANS. Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. While there are conflicting reports most studies suggest that use of oral contraceptives is not associated with an overall increase in the risk of developing breast cancer. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use. Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. 4. HEPATIC NEOPLASIA. Benign hepatic adenomas are associated with oral contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use especially with oral contraceptives of higher dose. Rupture of benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users approaches less than one per million users. 5. OCULAR LESIONS. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia, papilledema, or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately. 6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. The majority of recent studies also do not indicate a teratogenic effect, particularly in so far as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued until pregnancy is ruled out. 7. GALLBLADDER DISEASE. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens. 8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. This effect has been shown to be directly related to estrogen dose. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects prediabetic and diabetic women in particular should be carefully monitored while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see WARNINGS 1a and 1d), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users. 9. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in women taking oral contraceptives, and this increase is more likely in older oral contraceptive users and with extended duration of use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing progestational activity. Women with a history of hypertension or hypertension-related diseases, or renal disease, should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension between former and never users. 10. HEADACHE. The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause. 11. BLEEDING IRREGULARITIES. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent. 12. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. **PRECAUTIONS:** 1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine and liver function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3, increased norepinephrine-induced platelet aggregability. b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radio-immunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See WARNINGS section. 10. PREGNANCY. Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS. Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child. **INFORMATION FOR THE PATIENT: See Patient Package Insert. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS section). Thrombophlebitis and venous thrombosis with or without embolism. Arterial thromboembolism. Pulmonary embolism. Myocardial infarction. Cerebral hemorrhage. Cerebral thrombosis. Hypertension. Gallbladder disease. Hepatic adenomas or benign liver tumors. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea. Vomiting. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Amenorrhea. Temporary infertility after discontinuation of treatment. Edema. Melasma which may persist. Breast changes: tenderness, enlargement, secretion. Change in weight (increase or decrease). Change in cervical erosion and secretion. Diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome. Cataracts. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. Acne. Changes in libido. Colitis. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea and withdrawal bleeding may occur in females.

TRI - NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

BRIEF SUMMARY

TRI-NORINYL® 21-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 yellow-green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)
TRI-NORINYL® 28-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 yellow-green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 7 inert orange tablets)
BREVICON® 21-Day Tablets (norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)
BREVICON® 28-Day Tablets (21 norethindrone 0.5 mg with ethinyl estradiol 0.035 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 35 21-Day Tablets (norethindrone 1 mg with ethinyl estradiol 0.035 mg)
NORINYL® 1 + 35 28-Day Tablets (21 norethindrone 1 mg with ethinyl estradiol 0.035 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 50 21-Day Tablets (norethindrone 1 mg with mestranol 0.05 mg)
NORINYL® 1 + 50 28-Day Tablets (21 norethindrone 1 mg with mestranol 0.05 mg tablets followed by 7 inert tablets)
NOR-Q.D.® (norethindrone) Tablets 0.35 mg
ORAL CONTRACEPTIVE (O.C.) AGENTS

Indications: Prevention of pregnancy.

CONTRAINDICATIONS

Oral contraceptives should not be used in women who have the following conditions:
- Thrombophlebitis or thromboembolic disorders
- A past history of deep vein thrombophlebitis or thromboembolic disorders
- Cerebral vascular or coronary artery disease
- Known or suspected carcinoma of the breast
- Carcinoma of the endometrium, and known or suspected estrogen-dependent neoplasia
- Undiagnosed abnormal genital bleeding
- Cholestatic jaundice of pregnancy or jaundice with prior pill use
- Hepatic adenomas, carcinomas or benign liver tumors
- Known or suspected pregnancy

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia and gallbladder disease, although the risk of serious morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, hypercholesterolemia, obesity and diabetes.

Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

The information contained in this package insert is principally based on studies carried out in patients who used oral contraceptives with formulations containing 0.05 mg or higher of estrogen. The effects of long term use with lower dose formulations of both estrogens and progestogens remain to be determined.

Throughout this labeling, epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease. Relative risk, the *ratio* of the incidence of a disease among oral contraceptive users to that among non-users cannot be assessed directly from case control studies, but the odds ratio obtained is a measure of relative risk. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide not only a measure of the relative risk but a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and non-users. The attributable risk does provide information about the actual occurrence of a disease in the population.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS

a. Myocardial Infarction

An increased risk of myocardial infarction has been attributed to oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be 2 to 6. The risk is very low under the age of 30. However, there is the possibility of a risk of cardiovascular disease even in very young women who take oral contraceptives.

Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women 35 or older, with smoking accounting for the majority of excess cases.

Mortality rates associated with circulatory disease have been shown to increase substantially in smokers over the age of 35 and non-smokers over the age of 40 among women who use oral contraceptives.

Oral contraceptives may compound the effects of well-known risk factors for coronary artery disease, such as hypertension, diabetes, hyperlipidemias, hypercholesterolemia, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and impair oral glucose tolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see **WARNINGS,** section 9). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors.

b. Thromboembolism

An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. One cohort study has shown the relative risk to be somewhat lower, about 3 for new cases (subjects with no past history of venous thrombosis or varicose veins) and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease due to oral contraceptives is not related to length of use and disappears after pill use is stopped.

A 2- to 6-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. If feasible, oral contraceptives should be discontinued at least 4 weeks prior to and for 2 weeks after elective surgery and during and following prolonged immobilization. Since the immediate postpartum period also is associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than 4 to 6 weeks after delivery in women who elect not to breast feed.

c. Cerebrovascular diseases

An increase in both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes) has been shown in users of oral contraceptives. In general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users for both types of strokes while smoking interacted to increase the risk for hemorrhagic strokes.

In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for non-smokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk also is greater in women 35 or older and among smokers.

d. Dose-related risk of vascular disease from oral contraceptives

A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with some progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the nature and absolute amount of progestogens used in the contraceptives. The amount of both hormones should be considered in the choice of an oral contraceptive.

Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing the lowest estrogen content that produces satisfactory results for the individual.

e. Persistence of risk of vascular disease

There are three studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for 5 or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. Subarachnoid hemorrhage also has a significantly increased relative risk after termination of use of oral contraceptives. However, these studies were performed with oral contraceptive formulations containing 0.05 mg or higher of estrogen.

2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE

One study gathered data from a variety of sources which have estimated the mortality rates associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who use oral contraceptives have an increase in mortality greater than those using other methods of birth control. These facts must be weighed in conjunction with failure rates for other methods and the risk associated with subsequent pregnancy.

3. CARCINOMA OF THE BREAST AND REPRODUCTIVE ORGANS

Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. The evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone study also showed no latent effect on the risk of breast cancer for at least a decade following long term use. A few studies have shown a slightly increased relative risk of developing breast cancer, although the methodology of these studies, which included differences in examination of users and non-users and differences in age at start of use, has been questioned.

Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors.

In spite of many studies of the relationship between oral contraceptive use and breast or cervical cancers, a cause and effect relationship has not been established.

4. HEPATIC NEOPLASIA

Benign hepatic adenomas are associated with oral contraceptive use although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases per 100,000 for users, a risk that increases after 4 or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage.

Studies in the United States and Britain have shown an increased risk of developing hepatocellular carcinoma in long term (>8 years) oral contraceptive users. However, these cancers are extremely rare in the United States and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users is less than 1 per 1,000,000 users.

5. OCULAR LESIONS

There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately.

6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY

Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. More recent studies do not suggest a teratogenic effect, particularly insofar as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy.

The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion.

It is recommended that for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued if pregnancy is confirmed.

7. GALLBLADDER DISEASE

Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens.

8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS

Oral contraceptives have been shown to impair oral glucose tolerance. Oral contraceptives containing greater than 0.075 mg of estrogen cause glucose intolerance with impaired insulin secretion, while lower doses of estrogen may produce less glucose intolerance. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects, prediabetic and diabetic women should be carefully observed while taking oral contraceptives.

Some women may develop persistent hypertriglyceridemia while on the pill. As discussed earlier (see **WARNINGS,** sections 1a. and 1d.), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users.

9. ELEVATED BLOOD PRESSURE

An increase in blood pressure has been reported in women taking oral contraceptives. The incidence of risk also was reported to increase with continued use and among older women. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing concentrations of progestogens.

Women with a history of hypertension or hypertension-related diseases or renal disease should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives and there is no difference in the occurrence of hypertension among ever- and never-users.

10. HEADACHE

The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause.

11. BLEEDING IRREGULARITIES

Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first 3 months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding, as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out.

Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was pre-existent.

PRECAUTIONS

1. PHYSICAL EXAMINATION AND FOLLOW-UP

A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology and relevant laboratory tests. In case of undiagnosed, persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care.

2. LIPID DISORDERS

Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult.

3. LIVER FUNCTION

If jaundice develops in any woman receiving oral contraceptives the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function.

4. FLUID RETENTION

Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention.

5. EMOTIONAL DISORDERS

Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree.

6. CONTACT LENSES

Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist.

7. DRUG INTERACTIONS

Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines.

8. INTERACTIONS WITH LABORATORY TESTS

Certain endocrine and liver function tests and blood components may be affected by oral contraceptives:

a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG. Free T4 concentration is unaltered.

c. Other binding proteins may be elevated in serum.

d. Sex steroid binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged.

e. Triglycerides may be increased.

f. Glucose tolerance may be decreased.

g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives.

9. CARCINOGENESIS

See **WARNINGS** section.

10. PREGNANCY

Pregnancy Category X. See **CONTRAINDICATIONS** and **WARNINGS** sections.

11. NURSING MOTHERS

Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child.

INFORMATION FOR THE PATIENT

See **PATIENT LABELING.**

ADVERSE REACTIONS

An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see **WARNINGS** section):

• Thrombophlebitis • Arterial thromboembolism • Pulmonary embolism • Myocardial infarction • Cerebral hemorrhage • Cerebral thrombosis • Hypertension • Gallbladder disease • Hepatic adenomas, carcinomas or benign liver tumors

There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed:

• Mesenteric thrombosis • Retinal thrombosis

The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related:

• Nausea • Vomiting • Gastrointestinal symptoms (such as abdominal cramps and bloating) • Breakthrough bleeding • Spotting • Change in menstrual flow • Amenorrhea • Temporary infertility after discontinuation of treatment • Edema • Melasma which may persist • Breast changes: tenderness, enlargement, secretion • Change in weight (increase or decrease) • Change in cervical erosion and secretion • Diminution in lactation when given immediately postpartum • Cholestatic jaundice • Migraine • Rash (allergic) • Mental depression • Reduced tolerance to carbohydrates • Vaginal candidiasis • Change in corneal curvature (steepening) • Intolerance to contact lenses

The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted:

• Pre-menstrual syndrome • Cataracts • Changes in appetite • Cystitis-like syndrome • Headache • Nervousness • Dizziness • Hirsutism • Loss of scalp hair • Erythema multiforme • Erythema nodosum • Hemorrhagic eruption • Vaginitis • Porphyria • Impaired renal function • Hemolytic uremic syndrome • Budd-Chiari syndrome • Acne • Changes in libido • Colitis

OVERDOSAGE

Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

NON-CONTRACEPTIVE HEALTH BENEFITS

The following non-contraceptive health benefits related to the use of oral contraceptives are supported by epidemiological studies which largely utilized oral contraceptive formulations containing estrogen doses exceeding 0.035 mg of ethinyl estradiol or 0.05 mg of mestranol.

Effects on menses:

• Increased menstrual cycle regularity • Decreased blood loss and decreased incidence of iron deficiency anemia • Decreased incidence of dysmenorrhea

Effects related to inhibition of ovulation:

• Decreased incidence of functional ovarian cysts • Decreased incidence of ectopic pregnancies

Effects from long-term use:

• Decreased incidence of fibroadenomas and fibrocystic disease of the breast • Decreased incidence of acute pelvic inflammatory disease • Decreased incidence of endometrial cancer • Decreased incidence of ovarian cancer

Rev. August 1989

SYNTEX

Picture your OC patients here.

Your younger patients just starting contraception, because low impact norethindrone lowers the risk of acne and bloating.

Your career-oriented patients delaying childbearing, because reduced progestin helps avoid late cycle side effects, such as weight gain, headache, and depression.

Your older, nonsmoking patients restarting contraception, because Tri-Norinyl is the only multiphasic OC to lower progestin in the late cycle to minimize overall hormonal impact.

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

TRI-NORINYL®

Uniquely phased for all phases of a woman's reproductive life

Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. Please see adjacent page for brief summary of prescribing information. © 1990 Syntex Laboratories, Inc. 814-62-116-89

The only proven vaginal moisturizer

Bioadhesive technology clinically proven to end vaginal dryness

Statistically significant results from a multicenter clinical trial have shown that REPLENS increases moisture and improves epithelial integrity.* Through unique bioadhesive technology, REPLENS provides ongoing hydration of underlying vaginal tissue to end discomfort and painful intercourse.

Nonhormonal relief for more than 25 million women

Although most prevalent during menopause, vaginal dryness can occur during many stages of a woman's life. All these patients will appreciate your recommendation of REPLENS. REPLENS is a very natural way to bring back a feeling of youth and confidence many women thought they had lost forever.

Three times a week for full-time comfort

REPLENS relieves vaginal dryness, discomfort, and painful intercourse for up to 72 hours with a single application. REPLENS is greaseless, odorless, and nonirritating and packaged in disposable applicators for ease of use.

Call toll-free for information 1-800-749-1919.

CLINICAL SECTION

Clinical Opinion

Safe motherhood: Cesarean section or symphysiotomy? 1
Jos Van Roosmalen, MD, PhD
Leiden, The Netherlands

Symphysiotomy still has a place in the management of cephalopelvic disproportion, especially in the circumstances that prevail in the rural areas of developing countries.

Cost-effectiveness of intrapartum screening and treatment for maternal group B streptococci colonization 4
Daniel M. Strickland, COL, USAF, MC, Edward R. Yeomans, MAJ, USAF, MC, and Gary D. V. Hankins, LT COL, USAF, MC
Lackland Air Force Base, Texas

In the United States, intrapartum screening and treatment for group B streptococcal colonization is cost effective and offers the potential to avert a significant number of neonatal deaths and postpartum infections.

Clinical Articles

The effect of adjusting maternal serum α-fetoprotein levels for maternal weight in pregnancies with fetal open spina bifida 9
A. Myron Johnson, MD, Glenn E. Palomaki, BS, and James E. Haddow, MD
Scarborough, Maine

Adjustment of maternal serum α-fetoprotein levels for maternal weight slightly increases the detection rate of open spina bifida and reduces the false-positive rate.

Two-tier approach to biophysical assessment of the fetus 12
Martin S. Mills, MRCOG, David K. James, MD, and Sian Slade, RCM
Bristol, England

Acute-on-chronic fetal asphyxia can be excluded by a two-tier method of fetal assessment—nonstress test backed up by biophysical profile.

Sinusoidal fetal heart rate pattern during cardiopulmonary bypass 17
Ann B. Burke, MD, Dongzin Hur, MD, Jean C. Bolan, MD, Paul Corso, MD, and Fernando G. Resano, MD
Washington, D.C.

A sinusoidal fetal heart rate pattern was recorded during high-flow, low-pressure cardiopulmonary bypass; the child has developed normally for 2 years.

Risk factors for perinatal group B streptococcal disease after amniotic fluid colonization 19
Helayne M. Silver, MD, Ronald S. Gibbs, MD, Barry M. Gray, MD, and Hugh C. Dillon, MD
San Antonio, Texas, and Birmingham, Alabama

The development of perinatal group B streptococcal disease when amniotic fluid colonization already exists cannot be predicted by the clinical, serologic, or quantitative microbiologic factors studied.

Blood flow velocity and pulsatile diameter changes in the fetal descending aorta: A longitudinal study 26
Håkan Stale, MD, Gerhard Gennser, MD, PhD, and Karel Maršál, MD, PhD
Malmö, Sweden

Nonsimultaneous measurements of fetal aortic blood flow velocity and vessel diameter cause an underestimation of <8% in the calculation of volume blood flow.

Blood pressure measured telemetrically from home throughout pregnancy 30
Paul Mooney, MRCOG, Kevin J. Dalton, PhD, MRCOG, Helen E. Swindells, RGN, RM, Sally Rushant, RGN, RM, Wendy Cartwright, BA, and David Juett, BSc
Cambridge, England

The normal range of home blood pressure in pregnancy is defined with computerized telemetry; 68 randomly selected women were studied from 14 weeks' gestation until delivery.

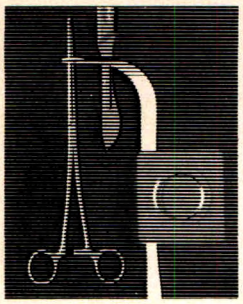
CEFOTAN® IM/IV



(cefotetan disodium)

In intra-abdominal and gynecologic infection due to indicated organisms

For Intravenous or Intramuscular Use
BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:
Urinary tract infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri,* and *Morganella morganii*).
Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli.*
Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli.*
Gynecologic infections caused by *Staphylococcus aureus** (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus* species (excluding enterococci), *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*), *Fusobacterium* species,* and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species*).
Intra-abdominal infections caused by *E coli, Klebsiella* species (including *K pneumoniae**), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*).
Bone and joint infections caused by *Staphylococcus aureus.**
*Efficacy for this organism in this organ system was studied in fewer than ten infections.

Specimens for bacteriological examination should be obtained in order to isolate and identify causative organisms and to determine their susceptibilities to cefotetan. Therapy may be instituted before results of susceptibility studies are known; however, once these results become available, the antibiotic treatment should be adjusted accordingly.

In cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other serious infections in which the causative organism has not been identified, it is possible to use CEFOTAN concomitantly with an aminoglycoside. Cefotetan combinations with aminoglycosides have been shown to be synergistic in vitro against many Enterobacteriaceae and also some other gram-negative bacteria. The dosage recommended in the labeling of both antibiotics may be given and depends on the severity of the infection and the patient's condition.

NOTE: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycosidic antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile.* Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment or poor nutritional state, the elderly and patients with cancer. Prothrombin times should be monitored in patients at risk and exogenous vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc.) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: Although to date nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels by Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approximately 8-16 times the usual adult human dose) on days 6-35 of life (thought to be

developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approximately 2-4 times the usual human dose) only 1 of 10 treated animals was affected, and the degree of degeneration was mild.

Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies, the following adverse effects were considered related to CEFOTAN therapy.
Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).
Hematologic laboratory abnormalities occurred in 1.4% of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).
Hepatic enzyme elevations occurred in 1.2% of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).
Hypersensitivity reactions were reported in 1.2% of patients and included rash (1 in 150) and itching (1 in 700).
Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500). During postmarketing experience with CEFOTAN, anaphylactic reactions and transient thrombocytopenia have been reported.

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dosage*	Every 12 hours
10-30	Usual Recommended Dosage*	Every 24 hours
<10	Usual Recommended Dosage*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Alternatively, the dosing interval may remain constant at 12 hour intervals, but the dose reduced to one-half the usual recommended dose for patients with a creatinine clearance of 10-30 mL/min, and one-quarter the usual recommended dose for patients with a creatinine clearance of less than 10 mL/min.

When only serum creatinine levels are available, creatinine clearance may be calculated from the following formula. The serum creatinine level should represent a steady state of renal function.

$$\text{Males:} \quad \frac{\text{Weight (kg)} \times (140 - \text{age})}{72 \times \text{serum creatinine (mg/100 mL)}}$$

Females: 0.9 × value for males

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. CEFOTAN is also available in a pharmacy bulk package of 10 g in 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.

1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21); 10 g in 100 mL vial (NDC 0038-0375-10).

β-Adrenergic receptor blockade in the management of pregnant women with mitral stenosis 37

Saad M. Al Kasab, FRCP, Taher Sabag, MD, Muayed Al Zaibag, FRCP, Mohamed Awaad, MRCOG, Issam Al Bitar, MD, Murtada A. Halim, MRCP, Moheeb A. Abdullah, MRCP, Maie Shahed, MRCP, Vijayaraghavan Rajendran, MRCP, and William Sawyer, MB, ChB

Riyadh, Saudi Arabia

With the use of β-blockade, pregnant women with moderately severe mitral stenosis can be safely managed to delivery without side effects on the neonate and with no maternal or neonatal mortality.

Cocaine-related maternal death 40

Gene Burkett, MD, Emmalee S. Bandstra, MD, Jay Cohen, MD, Bernard Steele, MD, and Diana Palow, RN

Miami, Florida

Sex-cocaine syndrome is postulated as a cause of maternal and fetal death.

Systemic cystic angiomatosis in pregnancy: A case presentation and review of the literature 42

A. Bardeguez, MD, M. Chatterjee, MD, M. Tepedino, MD, and B. Sicuranza, MD

Newark, New Jersey

An unusual case of systemic cystic angiomatosis with splenic involvement in pregnancy is described; diagnosis and management are discussed.

Interrelationship between atrial natriuretic factor concentrations and acute volume expansion in pregnant and nonpregnant women 45

Christos G. Hatjis, MD, Alexander D. Kofinas, MD, James P. Greelish, BA, Melissa Swain, RN, and James C. Rose, PhD

Winston-Salem, North Carolina, and Columbus, Ohio

Acute volume expansion with intravenous infusion of lactated Ringer's solution resulted in a significant increase in circulating atrial natriuretic factor levels in nonpregnant women but not in pregnant women at term.

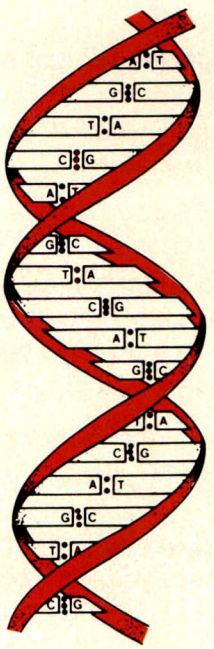
In utero detection of cardiac failure from an aneurysm of the vein of Galen 50

Philippe Jeanty, MD, PhD, Donna Kepple, RDMS, Pericles Roussis, MD, and Dinesh Shah, MD

Nashville, Tennessee

The prenatal diagnosis of an aneurysm of the vein of Galen by ultrasonography is demonstrated.

Morphologic study of changes of collagenous tissue in the amnion and cervix during prostaglandin-induced abortion and delivery 52



Yukio Manabe, MD, and Yoshinobu Yoshida, MD

Kyoto and Shiga, Japan

In our morphologic study, collagenous tissue in the amnion was not dissociated by prostaglandin treatment in contrast with that in the uterine cervix.

Vivigen Introduces Cystic Fibrosis Testing

- 1 in 25 Caucasians is a carrier of Cystic Fibrosis
- Direct DNA testing can now identify 70% of CF carriers
- For families at risk (those with a previous history of CF), indirect linkage or haplotype analysis can be performed

Physicians nationwide rely on Vivigen for thorough and accurate genetic testing, from chromosome analysis to biochemical and molecular genetics.

For more information about Vivigen's Cystic Fibrosis testing program, call 1-800-VIVIGEN or (505) 438-1111.

Immunohistochemical localization of prostaglandin H synthase in the female reproductive tract and endometriosis 57
Bradley J. Van Voorhis, MD, Phyllis C. Huettner, MD, Martin R. Clark, PhD, and Joseph A. Hill, MD
Boston, Massachusetts, and Chapel Hill, North Carolina

Prostaglandin H synthase is primarily localized in the surface epithelium of the reproductive tract and in the glandular epithelium of endometriosis and adenomyosis.

A case of Rh isoimmunization: Should threatened first-trimester abortion be an indication for Rh immune globulin prophylaxis? 63
Vanessa D. Dayton, MD, Deborah S. Anderson, BS, John T. Crosson, MD, and Stephen H. Cruikshank, MD
Minneapolis, Minnesota

This case of Rh isoimmunization after first-trimester bleeding without loss of the conceptus supports the argument for administering Rh immune globulin to Rh_o(D)-negative women in such instances.

Antisperm antibodies in women undergoing intrauterine insemination 65
Jeffrey M. Goldberg, MD, Paul L. Haering, Chad I. Friedman, MD, William G. Dodds, MD, and Moon H. Kim, MD
Columbus, Ohio

Intrauterine insemination does not induce significant antisperm antibody formation in women.

Expression of P-glycoprotein in epithelial ovarian cancer: Evaluation as a marker of multidrug resistance 69
Stephen C. Rubin, MD, Connie L. Finstad, PhD, William J. Hoskins, MD, Patricia E. Saigo, MD, Diane M. Provencher, MD, Mark G. Federici, BS, Thomas B. Hakes, MD, Maurie Markman, MD, Bonnie S. Reichman, MD, Kenneth O. Lloyd, PhD, and John L. Lewis, Jr., MD
New York, New York

P-Glycoprotein is expressed in only a small proportion of ovarian cancers; drug resistance in this tumor probably occurs through a mechanism other than expression of the MDR1 gene product.

Large cystic granulosa cell tumor: Case report 74
Chang-Hyun M. Choi, MD, and James R. Pritchard, DO
Massillon, Ohio

This case report describes one of the largest cystic granulosa cell tumors, weighing approximately 77 kg (170 pounds).

5-Fluorouracil exposure during the period of conception: Report on two cases 76
Lawrence D. Odom, MD, Leo Plouffe, Jr., MD, CM, and William J. Butler, MD
Augusta, Georgia, and Albany, New York

Two cases of exposure to 5-fluorouracil in the periconceptual period with normal neonatal outcomes are presented.

(Contents continued on page 13A)

To be continued...

Continuation...an excellent indicator of patient satisfaction.

The Ortho ALL-FLEX* Arcing Spring Diaphragm

- Easy to insert and position
- Easy to clean and maintain
- Easy to use with unscented, colorless, stainless GYNOL II* (2% nonoxynol-9) Contraceptive Jelly
- The combination for continuation—with 4 out of 5 patients continuing after 1 year†

Continuation...it's one reason why physicians continue to make ORTHO ALL-FLEX and GYNOL II the #1 prescribed diaphragm combination in America.‡

Ortho ALL-FLEX*

Arcing Spring

DIAPHRAGM

†Number of patients continuing the method for 12 consecutive months; data on file, Ortho Pharmaceutical Corporation.

‡Data on file, Ortho Pharmaceutical Corporation.

Consult the patient brochure for information on toxic shock syndrome (TSS) and wearing time.

Detection of fetal blood contamination by amniotic fluid obtained during cordocentesis 78
Noam Lazebnik, MD, Paula V. Hendrix, MD, Graham G. Ashmead, MD, Josephine W. Ashmead, MD, and Leon I. Mann, MD
Cleveland, Ohio

The fern test may aid in determination of contamination of fetal blood with amniotic fluid.

Comparisons of glycosylated and nonglycosylated amniotic fluid prolactins in normal second- and third-trimester pregnancies 81
John McCoshen, PhD, Eva Patalas, BSc(Med), Edith Markoff, PhD, David Lee, BSc, and Yang Ming, MD
Winnipeg, Manitoba, Canada, and La Jolla, California

The relative amount of glycosylated to nonglycosylated amniotic fluid prolactin changes during pregnancy and appears inversely related to immunoassayable prolactin concentrations.

Glucose tolerance in pregnancy: Ethnic variation and influence of body habitus 86
James R. Green, MD, Ivan G. Pawson, PhD, Laurie B. Schumacher, MPH, PhD, Jean Perry, MS, and Norman Kretchmer, MD, PhD
San Francisco, California

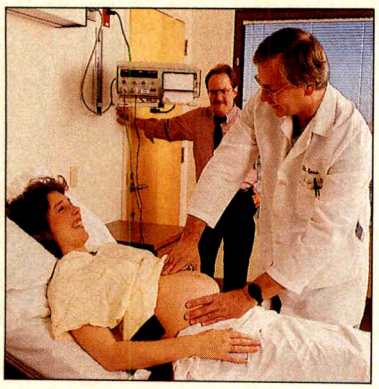
Glucose tolerance in late pregnancy differs among Hispanic, Chinese, black, and non-Hispanic white women and is significantly related to maternal age and body habitus.

Gestational diabetes mellitus: The prevalence of glucose intolerance and diabetes mellitus in the first two months post partum 93
Siri L. Kjos, MD, Thomas A. Buchanan, MD, Jeffrey S. Greenspoon, MD, Martin Montoro, MD, Gerald S. Bernstein, MD, and Jorge H. Mestman, MD
Los Angeles, California

In women with recent gestational diabetes, the prevalences of diabetes and impaired glucose tolerance in the puerperium were 10% and 9%, respectively, and were related to fasting glucose levels during pregnancy.

Indomethacin treatment for polyhydramnios and subsequent infantile nephrogenic diabetes insipidus 98
Leon G. Smith, Jr., MD, Brian Kirshon, MD, and David B. Cotton, MD
Houston, Texas

Polyhydramnios of unknown cause was treated with indomethacin; 6 months after birth, the infant had nephrogenic diabetes insipidus that also required indomethacin.



Risk factors for third-degree and fourth-degree perineal lacerations in forceps and vacuum deliveries 100
C. Andrew Combs, MD, PhD, Patricia A. Robertson, MD, and Russell K. Laros, Jr., MD
San Francisco, California

Factors associated with lacerations were midline episiotomy, nulliparity, arrest of descent, occipitoposterior, nonoutlet station, forceps, use of local anesthesia, and Asian race.

THE PERMANENTE MEDICAL GROUP

NORTHERN CALIFORNIA

The Permanente Medical Group, the largest multispecialty group practice in the U.S., is undergoing explosive growth in its Northern California region: the San Francisco Bay Area, Sacramento and the Central Valley. Our rapid increase in membership has created practice opportunities throughout the region for additional BC/BE Obstetricians and Gynecologists.

Our physician-managed group is part of the comprehensive Kaiser Permanente Medical Care Program. As a TPMG physician, you have access to the latest medical technology and resources, the support of colleagues in all subspecialties — and the opportunity to provide excellent health care without the burdens of managing a practice.

Join us in one of these facilities:

QUALITY

STABILITY

LEADERSHIP

GROWTH

SUPPORT

REWARDS

Santa Rosa — Opening new hospital featuring seven LDR's. Ten OB/GYN physicians and five nurse practitioners. Specialties include infertility, colposcopy, laser surgery and hysteroscopy. Call required once every nine nights. In Northern California's wine country, one hour north of San Francisco.

Santa Clara/Milpitas/Sunnyvale — 28 member department includes 3 perinatologists, GYN oncologist and reproductive endocrinologist. Ongoing clinical research. Our academic-oriented facility has an independent fully-accredited OB/GYN residency and serves as a core rotation for Stanford Medical Students. Academic appointments possible.

San Jose/Gilroy — Our 18 OB/GYN physicians average 3,000 deliveries per year and offer a full range of services including infertility, dysplasia and gyn-urology. On call approximately three nights per month. In-house Level II nursery; prenatal service shared with our nearby Santa Clara medical center. Satellite office in Gilroy. Located south of San Francisco and about one hour from the Monterey coast. The surrounding hills create a pleasant environment in which to live and work.

Hayward/Fremont — Full range of OB/GYN services with Level III L&D/ICN, 3000 deliveries yearly. Full time staff includes perinatologist and four neonatologists. Medical center and associated medical office located on east shore of San Francisco Bay with easy access to entire Bay Area.

Walnut Creek — Department of 15 physicians, a perinatologist and seven nurse practitioners. Two physicians on call daily. Teaching responsibilities for third year residents affiliated with the University of California at San Francisco. Clinical appointments at UCSF also available. Expansion plans include a large ICN, and within five years, a completely new hospital.

Martinez/Antioch — Southern California climate, Northern California charm, Bay Area location. Primarily in/outpatient GYN, outpatient OB. Seven physicians and four nurse practitioners in office and hospital practice. Deliver at the Walnut Creek Medical Center. High-risk pregnancy clinic at Martinez. Labor room call once or twice a month.

Vallejo/Fairfield/Napa — Seventeen physicians and four nurse practitioners at these facilities. Approximately 2,900 deliveries performed each year at the Vallejo medical center. Usual call is every eighth night. Affiliated with David Grant Medical Center residency program at Travis Air Force Base. Our area offers diverse lifestyle options, with both recreational and cultural attractions nearby.

San Rafael/Petaluma — OB/GYN services are available at both the San Rafael Medical Center and the new Petaluma medical offices, which opened in January of 1989.

South Sacramento — Eight physicians and four nurse practitioners serve 104,000 members in fast-growing Central Valley area. Planning new family-oriented L&D facilities.

KAISER PERMANENTE
Good People. Good Medicine.

TPMG offers many benefits: scheduled time off with cross-coverage provided by your colleagues, continuing education, malpractice insurance, a substantial retirement program and special arrangements for physicians transferring from established practice. For complete information, call or send CV to: The Permanente Medical Group, Inc., Richmond Prescott, M.D., Physician Recruitment Services, Dept. AJOG-8346, 1814 Franklin, 4th Floor, Oakland, CA 94612. (800) 777-4912. EOE

A comparison of tocolysis with nifedipine or ritodrine: Analysis of efficacy and maternal, fetal, and neonatal outcome 105
James E. Ferguson II, MD, Donald C. Dyson, MD, Thomas Schutz, BA, and David K. Stevenson, MD
Stanford and Santa Clara, California

Tocolysis with either nifedipine or ritodrine appears to be equally efficacious; however, maternal side effects were less common when nifedipine was administered.

Discrepancy in the diagnoses of hydatidiform mole by macroscopic and microscopic findings and the deoxyribonucleic acid fingerprint method 112
Hiroaki Takahashi, MD, Koji Kanazawa, MD, Toshihiko Ikarashi, MD, Norihito Sudo, MD, and Kenichi Tanaka, MD
Niigata, Niigata, Japan

A case of partial hydatidiform mole diagnosed by histologic findings was revealed to be complete hydatidiform mole by DNA fingerprinting.

Autogenic masculinization 114
Margaret R. Punch, MD, and Rudi Ansbacher, MD, MS
Ann Arbor, Michigan

A case of self-treatment with large doses of topical testosterone resulting in marked masculinization and secondary amenorrhea is reported.

Vulvar ulcer of unknown etiology in a human immunodeficiency virus–infected woman: Response to treatment with zidovudine 116
Jean Marie Covino, RPA, and William M. McCormack, MD
Brooklyn, New York

This case report describes a human immunodeficiency virus–infected woman with a chronic vulvar ulcer of unknown cause that healed in association with zidovudine treatment.

Endometrial assessment by vaginal ultrasonography before endometrial sampling in patients with postmenopausal bleeding 119
S. R. Goldstein, MD, M. Nachtigall, MD, J. R. Snyder, MD, and L. Nachtigall, MD
New York, New York

A thin (≤5 mm) "pencil line" endometrial echo by vaginal probe ultrasonography in patients with postmenopausal bleeding appears to be uniformly associated with tissue insufficient for diagnosis on endometrial sampling.

Transabdominal and transvaginal ultrasonography in the diagnosis of ectopic pregnancy: A comparative study 123
Asko I. Kivikoski, MD, DSc, Carolyn M. Martin, MD, and James S. Smeltzer, MD
St. Louis, Missouri

Transvaginal ultrasonography identified an ectopic gestational sac more frequently than did transabdominal ultrasonography in operatively proved ectopic pregnancies, thus allowing earlier conservative intervention.

Contents continued from page 15A

Niemann-Pick disease associated with nonimmune hydrops fetalis 128
Israel Meizner, MD, Arie Levy, MD, Rivka Carmi, MD, and Charles Robinsin, MD
Beer-Sheva, Israel

Niemann-Pick disease is added to the list of metabolic disorders associated with nonimmune hydrops fetalis.

Risk factors for preterm premature rupture of fetal membranes: A multicenter case-control study 130
James H. Harger, MD, Ann W. Hsing, PhD, Ruth E. Tuomala, MD, Ronald S. Gibbs, MD, Philip B. Mead, MD, David A. Eschenbach, MD, G. Eric Knox, MD, and B. Frank Polk, MD, MSc
Pittsburgh, Pennsylvania, Baltimore, Maryland, Boston, Massachusetts, San Antonio, Texas, Burlington, Vermont, Seattle, Washington, and Minneapolis, Minnesota

A multicenter case-control study revealed that preterm premature rupture of membranes was significantly correlated with cigarette smoking and with antepartum vaginal bleeding.

Necrotizing fasciitis of the total abdominal wall after sterilization by partial salpingectomy 138
John P. Cederna, MD, Brian W. Davies, MD, Stephen A. Farkas, MD, Joseph A. Sonta, MD, and Teddy Sworniowski, MD
Lewiston, Maine, and Barbertown, Akron, and Rootsdown, Ohio

Development of necrotizing fasciitis in a healthy young patient after routine tubal sterilization by minilaparotomy is reported; treatment of the patient and a review of literature are also discussed.

Relationship between plasma calcium fractions, other bone-related variables, and serum follicle-stimulating hormone levels in premenopausal, perimenopausal, and postmenopausal women 140
B. E. Christopher Nordin, MD, Howard A. Morris, PhD, Allan G. Need, MD, Michael Horowitz, PhD, and William G. Robertson, PhD
Adelaide, Australia, and Riyadh, Saudi Arabia

The menopausal rise in plasma calcium is mainly due to the complexed fraction and does not occur until levels of follicle-stimulating hormone exceed 50 to 60 U/L.

Survival and outcome of infants weighing <800 grams at birth 146
Evelyn G. Lipper, MD, Gail S. Ross, PhD, and Peter A. M. Auld, MD, and Marc B. Glassmann, PhD
New York and Bronx, New York

Stepwise logistic regression analysis demonstrated that 5-minute Apgar score and initial pH predicted mortality in a cohort of infants <800 gm at birth; outcome studies of surviving infants revealed a 72% incidence of developmental abnormality.

The differential neonatal morbidity of the intrauterine growth retardation syndrome 151
José Villar, MD, MPH, Mercedes de Onis, MD, PhD, Edgar Kestler, MD, MSc, Fernado Bolaños, MD, Rolando Cerezo, MD, and Heinz Bernedes, MD, MHS
Bethesda, Maryland, Atlanta, Georgia, and Guatemala, Guatemala

Disproportionate infants with intrauterine growth retardation had between a 1.6 and a 12.5 times higher risk of several indicators of early neonatal morbidity than proportionate infants with intrauterine growth retardation.

Contents

Growth of linear parameters in trisomy 18 fetuses 158
Sabine Droste, MD, Jack FitzSimmons, MD, Julie Pascoe-Mason, BS, and Thomas H. Shepard, MD
Seattle, Washington, and Madison, Wisconsin

Crown-rump, foot, and long-bone lengths are significantly reduced in fetuses with trisomy 18.

Current Development

Recurrent adverse pregnancy outcome and antiphospholipid antibodies 162
E. Albert Reece, MD, Sandro Gabrielli, MD, Mark T. Cullen, MD, Xue-Zhong Zheng, MD, John C. Hobbins, MD, and E. Nigel Harris, MPhil, MD, DM
New Haven, Connecticut, and Louisville, Kentucky

Circulating antiphospholipid antibodies are shown to be associated with recurrent adverse pregnancy outcome; therapeutic prophylaxis may improve outcome.

BASIC SCIENCE SECTION

The effect of adrenocorticotropic hormone infusion on subsequent pituitary response in the sheep fetus 170
William V. Cuthrell, MD, James C. Rose, PhD, and Paul J. Meis, MD
Winston-Salem, North Carolina

Pretreatment with adrenocorticotropic hormone decreases pituitary response in the sheep fetus.

Changes in platelet angiotensin II binding sites associated with the human menstrual cycle 175
Philip N. Baker, BM, Fiona Broughton Pipkin, DPhil, and E. Malcolm Symonds, MD
Nottingham, England

The human menstrual cycle was associated with a reduction in platelet angiotensin II binding sites.

Preventing cervical conization by achieving satisfactory colposcopy with hygroscopic cervical dilators 176
Jeffrey L. Stern, MD, Carol Major, MD, and Linda Van Le, MD
San Francisco, California, and Milwaukee, Wisconsin

Dilapan allowed satisfactory colposcopy and avoided cervical conization in 17 of 18 women with abnormal cervical cytologic findings.

Sharing of human leukocyte antigens in primary and secondary recurrent spontaneous abortions 178
Hong-Nerng Ho, MD, Thomas J. Gill III, MD, Rhone-Phong Nsieh, BS, Hon-Jou Hsieh, MD, and Tzu-Yao Lee, MD
Taipei, Taiwan, and Pittsburgh, Pennsylvania

The primary aborters shared HLA-A, DQ, and three or more of the HLA-A, B, DR, DQ antigens; the secondary aborters shared three or more of the HLA-A, B, DR, DQ antigens.

Studies of the spontaneous motility and the effect of histamine on isolated myometrial strips of the nonpregnant human uterus: The influence of various uterine abnormalities 189

Inocencia Martinez-Mir, MD, PhD, Luis Estañ, MD, PhD, Francisco J. Morales-Olivas, MD, PhD, and Elena Rubio, MD, PhD

Valencia, Spain

We emphasize the importance of uterine pathology and menopause in the spontaneous motility of the isolated strips of human corpus uteri.

A new tocolytic agent: Development of an oxytocin antagonist for inhibiting uterine contractions 195

Laird Wilson, Jr., PhD, Michael T. Parsons, MD, Luella Ouano, MD, and George Flouret, PhD

Chicago, Illinois

An oxytocin antagonist has been developed that has the potential of inhibiting preterm labor.

Differential sensitivities of fetal muscle groups to *d*-tubocurarine 202

Hazel H. Szeto, MD, PhD, and Donald J. Hinman, PhD

New York, New York

An investigation of the relative sensitivities of different fetal muscles to *d*-tubocurarine revealed that the median effective dose for neuromuscular blockade of extraocular muscles/nuchal muscle/diaphragm was 1:2.5:6.

Immunoglobulin G fractions from patients with antiphospholipid antibodies cause fetal death in BALB/c mice: A model for autoimmune fetal loss 210

D. Ware Branch, MD, Donald J. Dudley, MD, Murray D. Mitchell, DPhil, Kathryn A. Creighton, BS, Thomas M. Abbott, MD, Elizabeth H. Hammond, MD, and Raymond A. Daynes, PhD

Salt Lake City, Utah

Intraperitoneal injection of immunoglobulin G from patients with pregnancy loss and antiphospholipid antibodies causes fetal death in pregnant mice.

In vitro effect of RU 486 on sperm-egg interaction in mice 216

Subhash C. Juneja, PhD, and Melvin G. Dodson, MD, PhD

Johnson City, Tennessee

RU 486 caused a dose-dependent reduction of the fertilization rate in vitro in mice; increased perivitelline polyspermy was observed under the influence of RU 486.

Relationship between the ovine fetal umbilical artery blood flow waveform and umbilical vascular resistance 222

Glenn L. Irion, PhD, and Kenneth E. Clark, PhD

Cincinnati, Ohio

Systolic/diastolic ratios measured directly from the common umbilical artery of ovine fetuses with transit-time Doppler flow probes did not consistently vary with umbilical vascular resistance when altered by vasoactive agents.

Contents

Role of the endothelium in adrenergic responses of mesenteric artery rings of pregnant rats 229
Angèle Parent, BSc, Ernesto L. Schiffrin, MD, PhD, and Jean St-Louis, PhD
Montreal, Quebec, Canada

The endothelium influences the vascular adrenergic responses, but this influence is not modified during pregnancy in the rat.

HBcAg identification in the placental cytotypes of symptom-free HBsAg-carrier mothers: A study with the immunoperoxidase method 235
Giovanna Lucifora, MD, Fabio Martines, PhD, Santina Calabro', MD, Giuseppe Carroccio, MD, Amalia Brigandi', MD, and Renato de Pasquale, MD
Messina, Italy

HBcAG was demonstrated by immunoperoxidase staining in placentas of asymptomatic HBsAG-carrier mothers.

Calcium every day
Aerobics every wee
Bone loss every yea

She needs PREMARIN to help prevent further bone loss

Calcium[1] and exercise are not enough to prevent post-menopausal osteoporosis, since estrogen deficiency is the primary cause.[2] PREMARIN is the only brand of estrogen indicated to prevent further bone loss and in a recently published study has been shown to reduce the risk of hip fractures by as much as 66%.[3]

Early PREMARIN therapy offers the best protection

The most significant rate of bone loss occurs in early menopause. PREMARIN can help maintain bone mass, preventing the progression of osteoporosis and its consequences.

Protection continues as long as estrogen therapy continues

Clinical studies show that within three years of menopause when therapy is withdrawn, bone loss begins again.[4]

PREMARIN®

(conjugated estrogens tablets)

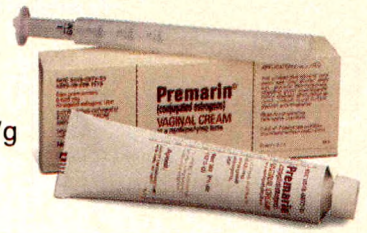
Proven benefits for menopause and beyond

See important information on adjacent page.

For moderate-to-severe vasomotor symptoms and for osteoporosis

PREMARIN®
(conjugated estrogens tablets)

0.3 mg 0.625 mg 0.9 mg 1.25 mg 2.5 mg



The appearance of these tablets is a trademark of Wyeth-Ayerst Laboratories.

For atrophic vaginitis

PREMARIN®
(conjugated estrogens)

Vaginal Cream

0.625 mg/g

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULARS.)*

PREMARIN® Brand of conjugated estrogens tablets, USP
PREMARIN® Brand of conjugated estrogens Vaginal Cream, in a nonliquefying base

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA. Close clinical surveillance of all women taking estrogens is important. Adequate diagnostic measures including endometrial sampling when indicated should be undertaken to rule out malignancy in all cases of undiagnosed persistent or recurring abnormal vaginal bleeding. There is currently no evidence that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.
2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY. Estrogen therapy during pregnancy is associated with an increased risk of congenital defects in the reproductive organs of the male and female fetus, an increased risk of vaginal adenosis, squamous-cell dysplasia of the uterine cervix, and vaginal cancer in the female later in life. The 1985 DES Task Force concluded that women who used DES during their pregnancies may subsequently experience an increased risk of breast cancer. However, a causal relationship is still unproven, and the observed level of risk is similar to that for a number of other breast cancer risk factors.

There is no indication for estrogen therapy during pregnancy. Estrogens are ineffective for the prevention or treatment of threatened or habitual abortion.

DESCRIPTION: PREMARIN (conjugated estrogens, USP) contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters. Tablets are available in 0.3 mg, 0.625 mg, 0.9 mg, 1.25 mg, and 2.5 mg strengths of conjugated estrogens. Cream is available as 0.625 mg conjugated estrogens per gram.

INDICATIONS AND USAGE: Moderate-to-severe vasomotor symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause and they should not be used to treat these conditions.) Prevention and management of osteoporosis (abnormally low bone mass). Atrophic vaginitis. Atrophic urethritis. Hypoestrogenism due to hypogonadism, castration or primary ovarian failure.

PREMARIN (conjugated estrogens) Vaginal Cream is indicated in the treatment of atrophic vaginitis and kraurosis vulvae.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected pregnancy (see Boxed Warning). 2. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 3. Known or suspected estrogen-dependent neoplasia. 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. Estrogen replacement therapy has not been reported to increase the risk of thrombophlebitis and/or thromboembolic disease. However, there is insufficient information regarding women who have had previous thromboembolic disease.

PREMARIN Tablets and Vaginal Cream should not be used in patients hypersensitive to their ingredients.

WARNINGS: Some studies suggest a possible increased incidence of breast cancer in women taking higher doses of estrogen for prolonged time periods. The majority of studies have not shown an association with usual estrogen replacement doses. Endometrial cancer risk among estrogen users was about 4-fold or greater than in non-users, and appears dependent on treatment duration and estrogen dose. In patients on combined estrogen-progestin therapy, this risk appears to be decreased. (See PRECAUTIONS below.)

Estrogen therapy during pregnancy is associated with an increased risk of fetal congenital reproductive tract disorders.

A 2.5-fold increase in the risk of surgically confirmed gall bladder disease in women receiving postmenopausal estrogens has been reported.

Large doses of estrogen such as those used to treat prostate and breast cancer have been shown to increase the risk of non-fatal myocardial infarction, pulmonary embolism, and thrombophlebitis in men. This cannot necessarily be extrapolated to women. However, to avoid theoretical cardiovascular risk caused by high estrogen doses, the doses for estrogen replacement therapy should not exceed the recommended dose.

Blood pressure should be monitored with estrogen use, especially if high doses are used.

Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: The addition of a progestin for 7 or more days of a cycle of estrogen administration reportedly lowers the incidence of endometrial hyperplasia. Studies of endometrium suggest that 10 to 13 days of progestin are needed to provide maximal endometrial maturation and elimination of hyperplastic changes. Additional risk, such as adverse effects on carbohydrate and lipid metabolism, may be associated with the inclusion of progestin in estrogen replacement regimens. The choice of progestin and dosage may be important in minimizing these adverse effects.

Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Conditions influenced by fluid retention, such as asthma, epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding and mastodynia. Pre-existing uterine leiomyomata may increase in size during estrogen use. Estrogens should be used with care in patients with impaired liver function, renal insufficiency, or metabolic bone diseases associated with hypercalcemia.

The following drug/laboratory test interactions have been reported, some only with estrogen-progestin combinations (oral contraceptives):

1. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.
2. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by T_4 levels determined by column or by radioimmunoassay. Free T_3 resin uptake is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered.
3. Impaired glucose tolerance.
4. Reduced response to metyrapone test.
5. Reduced serum folate concentration.

MUTAGENESIS AND CARCINOGENESIS: Long-term, continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver.

PREGNANCY CATEGORY X: Estrogens should not be used during pregnancy. See **CONTRAINDICATIONS** and Boxed Warning.

NURSING MOTHERS: As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy; changes in vaginal bleeding pattern and abnormal withdrawal bleeding or flow, breakthrough bleeding, spotting, increase in size of uterine fibromyomata, vaginal candidiasis, change in amount of cervical secretion; tenderness or enlargement of breasts; nausea, vomiting, abdominal cramps, bloating, cholestatic jaundice; chloasma or melasma that may persist when drug is discontinued, erythema multiforme, erythema nodosum, hemorrhagic eruption, loss of scalp hair, hirsutism; steepening of corneal curvature, intolerance to contact lenses; headache, migraine, dizziness, mental depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria; edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea and vomiting.

DOSAGE AND ADMINISTRATION:

PREMARIN® Brand of conjugated estrogens tablets, USP

1. *Given cyclically for short-term use only.* For treatment of moderate-to-severe vasomotor symptoms, atrophic vaginitis, or atrophic urethritis associated with the menopause (0.3 mg to 1.25 mg or more daily). The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible. Administration should be cyclic (eg, three weeks on and one week off). Attempts to discontinue or taper medication should be made at three- to six-month intervals.
2. *Given cyclically:* Hypoestrogenism. Osteoporosis.

Hypoestrogenism due to: Female hypogonadism—2.5 mg to 7.5 mg daily in divided doses for 20 days followed by 10 day rest period. If bleeding does not occur by the end of this period, the same dosage schedule is repeated. Female castration or primary ovarian failure—1.25 mg daily, cyclically. Adjust upward or downward according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Osteoporosis—0.625 mg daily. Administration should be cyclic (eg, three weeks on and one week off).

PREMARIN® Brand of conjugated estrogens Vaginal Cream

Given cyclically for short-term use only. For treatment of atrophic vaginitis or kraurosis vulvae.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Attempts to discontinue or taper medication should be made at three- to six-month intervals.

Usual dosage range: 2 g to 4 g daily, intravaginally, depending on the severity of the condition.

Patients with an intact uterus who are treated with either PREMARIN Tablets or Vaginal Cream should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1988;108:258-65. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL, and in more detail in the *Guide to Writing for the American Journal of Obstetrics and Gynecology*. The latter may be obtained from Mosby–Year Book, Inc., or the Editors on request.

Manuscript submission. Manuscripts should be submitted to one of the three Editors as follows:

1. **Dr. Brewer**—all manuscripts originating from the southeastern quadrant of the United States or Canada and those presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation and The Society of Perinatal Obstetricians.

2. **Dr. Zuspan**—manuscripts from the northeastern quadrant of the United States and from Japan, Israel, Italy, and England, manuscripts written for Clinical Opinion and Current Development, and Letters to the Editors. Dr. Zuspan is responsible for manuscripts from The Society of Perinatal Obstetricians. Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. Donald R. Coustan, Department of Obstetrics and Gynecology, Women and Infants Hospital of Rhode Island, 101 Dudley St., Providence, RI 02905.

3. **Dr. Quilligan**—manuscripts from the north central states (including Ohio), states west of the Mississippi River, Hawaii, Alaska, and abroad (except Japan, Israel, Italy, and England). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.

Author's designation of reviewers. When authors submit their manuscripts, they may provide the names and addresses of three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. (The Checklist and Copyright Statement may be torn from the JOURNAL or photocopied for submission.) If not completed in full, it will be returned to the author for completion.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.

Previous publication. If a report by the same author(s) has been previously published in any medium that deals in any respect whatever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. The author(s) should inform the Editor of the circumstances of the two reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or

accepted manuscript. Articles previously published in another language will not be considered.

Human and animal experimentation. It is assumed by the Editors that manuscripts emanating from a particular institution are submitted with the approval of the requisite authority. Human experimentation that requires local institutional approval must have this approval *before the experiment is started* and approval must be so indicated in the Methods section of the submitted manuscript. Reports of experiments on animals must *state in the Methods section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed. The species of nonhuman animals used in an investigation must be named in the title, abstract, and key words of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or publisher, and the Editor(s) and publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of glossy prints of illustrations are required.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, and business and home telephone numbers of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, and business and home telephone numbers of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page and key words/phrases. On manuscript page 3 type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors.* Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

Estimating length of manuscripts

The length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A 4200-word text can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone make approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables are used, the length of the text should be adjusted accordingly.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Avoid duplication of text and supporting material. Emphasize only your important observations; do not compare your observations with those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number are allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (Ann Intern Med 1988;108:258-65). Journal titles should conform to abbreviations used in *Cumulated Index Medicus*.

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Fischermann E, Quilligan EJ, et al. Vaginal delivery following cesarean section—use of oxytocin augmentation and epidural anesthesia. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: James VHT, Folkerd EJ, Bonney RC, Beranek PA, Reed MJ. Factors influencing estrogen production and metabolism in postmenopausal women with endocrine cancer. In: van Herendael HB, Riphagen FE, Goessens L, van der Pas H, eds. The climacteric, an update. Lancaster, England: MTP Press, 1983:29.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. This signed permission must accompany the manuscript when it is submitted to the Editor. Abstracts are not acceptable as numbered references.

Illustrations and tables. Illustrations and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice.

A reasonable number of halftone and line illustrations will be reproduced without charge, but special arrangements must be made with the Editors for *color illustrations* at a cost of $525 per page (one side).

For *color photographs* submit original transparencies and two sets of unmounted prints on glossy (smooth-surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The *top, first author's last name,* and *figure number* must be indicated on the front of each transparency and the back of each print. Consistency in size of illustrations within the article is strongly preferred.

For *black-and-white illustrations* submit three sets of 3×4 inch (minimum) to 5×7 inch (maximum) unmounted, glossy photographic prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy photographic prints with good black-and-white contrast. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted.

Do not use paper clips or mar the surface of prints in any way.

Figures must be cited consecutively in the text in Arabic numerals and identified thusly on the back of the print (gummed label with): author(s) name(s), title of article, number, and top marked clearly.

Figures will be returned only on request by the author.

Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Captions should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. *If a table or any part thereof has been taken from copyrighted material, a legend to the table must give full credit to the original source.* Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Legends to illustrations. Legends for all figures must be typed double-spaced on paper separate from the text of the manuscript, and these pages must be numbered in sequence after the references. Titles should be included in the legend, *not* on the print. Original magnifications should be provided. *If an illustration has been taken from copyrighted material, the legend must give full credit to the original source.*

Computer-generated illustrations. *Black-and-white illustrations* submitted must be legible and clearly printed in jet-black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend for the illustration should not appear on the print. On the back of each print the name of the first author and the figure number should be given and the top indicated. Original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color illustrations* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color illustrations. The preparation and submitting of color prints should follow the preceding guidelines for black-and-white computer-generated illustrations.

Permissions. Direct quotations, tables, or illustrations that have appeared in copyrighted material must be accompanied by *written permission* for their use from the copyright owner and original author along with complete information as to source. Photographs of identifiable persons must be accompanied by signed releases or else all recognizable features masked.

Requirements for special sections

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article.

Clinical Opinion. Limit of 3000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Letters to the Editors. Letters to the Editors must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words [excluding references, name(s) and address(es) of the signer(s), and the phrase "To the Editors"]. The submitted Letter to the Editors must be accompanied by a signed copyright statement. If there are two or more signers of the Letter to the Editors, one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all co-signers." These requirements apply to all types of Letters to the Editors. Letters should be sent to Dr. Zuspan.

Two types of correspondence will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie. No books will be returned.

Reprints

Reprints of articles must be obtained from the author. The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (314) 872-8370.

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms **must be completed** and sent with each submitted manuscript. If **not** completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

—The original and two copies of the manuscript are submitted.
—The appropriate signed completed checklist and assignment of copyright signed by **all** authors accompany the manuscript.
—Three sets of unmounted glossy photographic prints are submitted, properly numbered and labeled on the back of each print.
—Three sets of computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back are submitted. None are dot matrix or photographic prints.
—Human experimentation has been approved by the local institution as stated in the Methods section.
—Guidelines for the care and use of animals approved by the institution have been followed as indicated in the Methods section.
—The covering letter with essential information is with the manuscript.
—All elements of the manuscript are typed double-spaced on bond paper with 1-inch margins at top, bottom, and sides.
—All pages are numbered in the following order: title page, condensation, abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.
—Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.
—Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any co-authors that might pose a conflict of interest is described.

Previous publications

—Enclosed with the submitted manuscript are two reprints each of articles the author or co-authors have previously published or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.

Title page

—These elements are given in the following sequence, and are typed double-spaced.
—Title
—Author(s) name(s) and highest academic degree(s)
—City(ies), state(s), and country other than U.S. in which the study was conducted are given
—The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the author(s) institutional affiliation at the time of the study is indicated
—Acknowledgment of financial support is cited
—Name, address, and business and home telephone numbers of author to whom requests for reprints are to be sent
—Reprints will not be available. This has been stated on the title page
—Since the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, and business and home telephone numbers have been added
—At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract

—The abstract is typed double-spaced with required margins (on page 3) headed by the title and the author(s) name, not exceeding 150 words. For case reports and brief communications the limit of 50 words is not exceeded.
—Three to five key words or short phrases are placed beneath the abstract on page 3.

Tables

—Each table headed by a caption and numbered in Roman numerals is typed double-spaced on a separate page.
—Tables are cited in sequence in the text.

Figures

—Are numbered in Arabic numerals and are cited in numerical sequence in the text.

—Original transparencies of **color photographs** appropriately numbered and identified are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

References

—Are typed double-spaced.

—Are numbered consecutively in the order they are cited in the text.

—The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors were followed.

—Abstracts, personal communications, and unpublished work are not used as numbered references but are mentioned in the text with the written approval of the person being quoted and the signed approval is enclosed.

A TRUSTED PART OF HER FAMILY PLANNING.

Proven Contraceptive Effectiveness with:

- ▷ Dependable cycle regularity...the cornerstone of the Wyeth norgestrel family of OCs
- ▷ Low 30 mcg estrogen dose
- ▷ No generic available

L O W D O S E

LO/OVRAL® 30 mcg

each tablet contains 0.3 mg norgestrel and 30 mcg ethinyl estradiol, Wyeth

Prescribe it with confidence

Serious as well as minor adverse reactions have been reported following the use of all oral contraceptives. See prescribing information.
See important information on adjacent page.

© 1990, Wyeth-Ayerst Laboratories.

LO/OVRAL® 30 mcg

each tablet contains 0.3 mg norgestrel and 30 mcg ethinyl estradiol, Wyeth

Prescribe it with confidence

IN BRIEF:

Indications and Usage—LO/OVRAL* is indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OC's) as a method of contraception.

Contraindications—OC's should not be used in women with any of the following conditions:

1. Thombophlebitis or thromboembolic disorders.
2. A past history of deep-vein thrombophlebitis or thromboembolic disorders.
3. Cerebral-vascular or coronary-artery disease.
4. Known or suspected carcinoma of the breast.
5. Known or suspected estrogen-dependent neoplasia.
6. Undiagnosed abnormal genital bleeding.
7. Known or suspected pregnancy (see Warning No. 5).
8. Benign or malignant liver tumor which developed during use of OC's or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems*—An increased risk of thromboembolic and thrombotic disease associated with use of OC's is well established. Three principal studies in Great Britain and 3 in the U.S. have demonstrated increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OC's are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION (MI)—An increased risk of MI associated with use of OC's has been reported, confirming a previously suspected association. These studies, conducted in the UK, found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of pre-eclamptic toxemia) the higher the risk of developing MI, regardless of whether the patient was an OC user or not. OC's, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to MI) are about twice as likely to have a fatal MI as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal MI compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, amount of smoking is also an important factor. In determining importance of these relative risks, however, baseline rates for various age groups must be given serious consideration. Importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; quite likely the same synergistic action exits, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse-reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to dose of estrogen in OC's. Preparations containing 100 mcg or more of estrogen were associated with higher risk of thromboembolism than those containing 50-80 mcg. Their analysis did suggest, however, that quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the U.S.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the UK estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OC's according to age, smoking habits, and duration of use. Overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 [ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000], risk being concentrated in older women, in those with long duration of use, and in cigarette smokers. It was not possible, however, to examine interrelationships of age, smoking, and duration of use, nor to compare effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess magnitude of relative risk for this younger group. Available data from a variety of sources have been analyzed to estimate risk of death associated with various methods of contraception. Estimates of risk of death for each method include combined risk of contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OC's) plus risk attributable to pregnancy or abortion in event of method failure. This latter risk varies with effectiveness of method. The study concluded that mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OC's in women over 40 who smoke. Lowest mortality is associated with condom or diaphragm backed up by early abortion. Risk of thromboembolic and thrombotic disease associated with OC's increases with age after about 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of pre-eclamptic toxemia, and especially cigarette smoking. Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders [e.g., thombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis]. Should any of these occur or be suspected, the drug should be discontinued immediately. A 4- to 6-fold increased risk of postsurgery thromboembolic complications has been reported in OC users.

If feasible, OC's should be discontinued at least 4 weeks before surgery of a type associated with increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Britain involving cerebrovascular disease and another in the U.S. concerning MI suggest an increased risk of these conditions in users of OC's persists after discontinuation of the OC's. In the British study, risk of cerebrovascular disease remained elevated in former OC users for at least 6 years after discontinuation. In the U.S. study, increased risk of MI persisted for at least 9 years in women 40- to 49-years-old who had used OC's for 5 or more years. Findings in both studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions*—There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with use of OC's. Discontinue OC's if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma*—Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in OC's, have been noted to increase incidence of mammary nodules, benign and malignant, in dogs. In humans, 3 case-control studies have reported an increased risk of endometrial carcinoma associated with prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OC's. Of cases found in women without predisposing risk factors (e.g., irregular bleeding at the time OC's were first given, polysystic ovaries), nearly all occurred in women who had used a sequential OC. These are no longer marketed. No evidence has been reported suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only OC's. Several studies have found no increase in breast cancer in women taking OC's or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women on OC's, found an excess risk in subgroups of OC users with documented benign breast disease. Reduced occurrence of benign breast tumors in users of OC's has been well documented. In summary, there is at present no confirmed evidence from human studies of increased risk of cancer associated with OC's. Close clinical surveillance of all women on OC's is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms should be monitored with particular care if they elect to use OC's.

4. *Hepatic Tumors*—Benign hepatic adenomas have been found to be associated with the use of OC's. One study showed that OC's with high hormonal potency were associated with higher risk than lower potency OC's. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users. Two studies relate risk with duration of use of OC's, the risk being much greater after 4 or more years' use. While hepatic adenoma is rare, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women on OC's. Relationship of these drugs to this type of malignancy is not known.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring*—Use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have increased risk of developing in later life a form of vaginal or cervical cancer ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence now that OC's further enhance risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OC's. Furthermore, 30 to 90% of such exposed women have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with use of other estrogens, it cannot be presumed they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with use of sex hormones, including OC's, in pregnancy. One case control study estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OC's, hormonal withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some exposures involved only a few days. Data suggest that risk of limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OC's. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OC's is unknown. It is recommended that, for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing OC's. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at time of first missed period, and further use of OC's should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and advisability of continuation of the pregnancy should be discussed. It is also recommended that women who discontinue OC's with intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this. The administration of progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease*—Studies report increased risk of surgically confirmed gallbladder disease in users of OC's and estrogens. In one study, increased risk appeared after 2 years' use and doubled after 4 or 5 years' use. In one of the other studies, increased risk was apparent between 6 and 12 months' use.

7. *Carbohydrate and Lipid Metabolic Effects*—Decrease in glucose tolerance has been observed in a significant percentage of patients on OC's. For this reason, prediabetic and diabetic patients should be carefully observed while on OC's. Increase in triglycerides and total phospholipids has been observed in patients on OC's; clinical significance of this finding remains to be defined.

8. *Elevated Blood Pressure*—Increase in blood pressure has been reported in patients on OC's. In some women, hypertension may occur within a few months of beginning OC's. In the 1st year of use, prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. Prevalence in users increases, however, with longer exposure, and in the 5th year of use is 2½ to 3 times the reported prevalence in the 1st year. Age is also strongly correlated with development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure on OC's. Hypertension that develops as a result of taking OC's usually returns to normal after discontinuing the drug.

9. *Headache*—Onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of OC's and evaluation of the cause.

10. *Bleeding Irregularities*—Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing OC's. In breakthrough bleeding, as in all cases of irregular vaginal bleeding, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another OC may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase risk of thromboembolic disease. Women with past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuing OC's. Women with these pre-existing problems should be advised of this possibility and encouraged to use other methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy*—Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding*—OC's given in the postpartum period may interfere with lactation and decrease quantity and quality of breast milk. Furthermore, a small fraction of the hormones in OC's has been identified in the milk of mothers on OC's; effects, if any, on the breast-fed child have not been determined. If feasible, defer OC's until infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OC's. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Pap smear and relevant laboratory tests.

As a general rule OC's should not be prescribed for longer than 1 year without another physical examination.

2. Under influence of estrogen-progestogen preparations, pre-existing uterine leiomyomata may increase in size.

3. Patients with history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while on OC's should stop OC's and use an alternate method to try to determine whether the symptom is drug-related.

4. OC's may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency.

5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while on OC's. If jaundice develops, OC's should be discontinued.

6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution.

7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. Clinical significance is undetermined.

8. Serum folate levels may be depressed by OC's. Since the pregnant woman is predisposed to development of folate deficiency and incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OC's, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency.

9. The pathologist should be advised of OC therapy when relevant specimens are submitted.

10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OC's: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling.

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis—See Warnings on carcinogenic potential of OC's.

Pregnancy—Category X. See Contraindications, Warnings.

Nursing Mothers—See Warnings.

Adverse Reactions—An increased risk of these serious adverse reactions has been associated with use of OC's (see Warnings): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.

There is evidence of an association between the following conditions and use of OC's although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients on OC's and are believed to be drug-related: nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea, amenorrhea during and after treatment, temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement, and secretion; change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening), intolerance to contact lenses.

The following adverse reactions have been reported in users of OC's, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OC's by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Safe motherhood: Cesarean section or symphysiotomy?

Jos van Roosmalen, MD, PhD

Leiden, The Netherlands

The place of symphysiotomy in the management of cephalopelvic disproportion is discussed on the basis of the existing literature, reviewing maternal mortality and morbidity after symphysiotomy and the vaginal delivery rate in a subsequent pregnancy after a previous symphysiotomy. These are compared with the outcome of cesarean section performed in similar circumstances. (AM J OBSTET GYNECOL 1990;163:1-4.)

Key words: Cesarean section, symphysiotomy, maternal mortality, subsequent vaginal delivery

At least 500,000 women die annually from the complications of abortion, pregnancy, and labor, and only recently maternal mortality has been recognized by the international community as a serious public health concern.[1-2] The World Health Organization, in collaboration with the United Nations Population Fund and the World Bank, in 1987 launched the "Safe Motherhood Campaign" to combat this appalling situation.

Apart from abortion, obstructed labor is one of the leading conditions on the road to maternal death. In a report from the World Health Organization[3] cesarean section was advocated in addition to other measures to reduce mortality resulting from obstructed labor.

On the other hand, cesarean section itself carries mortality and morbidity risks, especially in the conditions that prevail in the rural areas of developing countries where obstructed labor is most prevalent. The maternal mortality rate after cesarean section in different African hospitals is 1.8% (range, <0.6% to 5.0%) with approximately 3% in rural and 1% in teaching hospitals (Table I).[4] The mortality rate after cesarean section in women booked for delivery in a Nigerian teaching hospital (0.6%) is still six times higher than the mortality rate after cesarean section at present in the Western world (0.1%).[5-6] Even lower mortality rates have been reported in the United States: six per 10,000 operations.[7] On the other hand, serious underreporting of maternal deaths after cesarean section has been detected as well.[8]

One remote risk concerns rupture of the uterine scar in a subsequent pregnancy, and this is a rather frequent complication that often leads to perinatal death and serious maternal morbidity and even mortality (Table I).

Symphysiotomy has been proffered as an alternative to cesarean section in some cases of obstructed labor. Symphysiotomy is the artificial separation of the symphysis pubis with a scalpel to enlarge the pelvic diameters to facilitate the process of birth. It has never become popular because of its urologic and orthopedic complications and is viewed as an out-of-date or second-class obstetric intervention in the Western world and even among the medical profession in Third World countries. However, experience with the procedure does not warrant such a negative attitude and as an illustration recent data on mortality and morbidity after symphysiotomy are presented in this article.

Maternal mortality after symphysiotomy at present is almost negligible; in a series of 1752 symphysiotomies only three women died and none of these deaths was related to the symphysiotomy procedure (Table I). Two women died from eclampsia and one death occurred after cesarean section when symphysiotomy failed to deliver the baby.

In that series of 1752 symphysiotomies, serious ma-

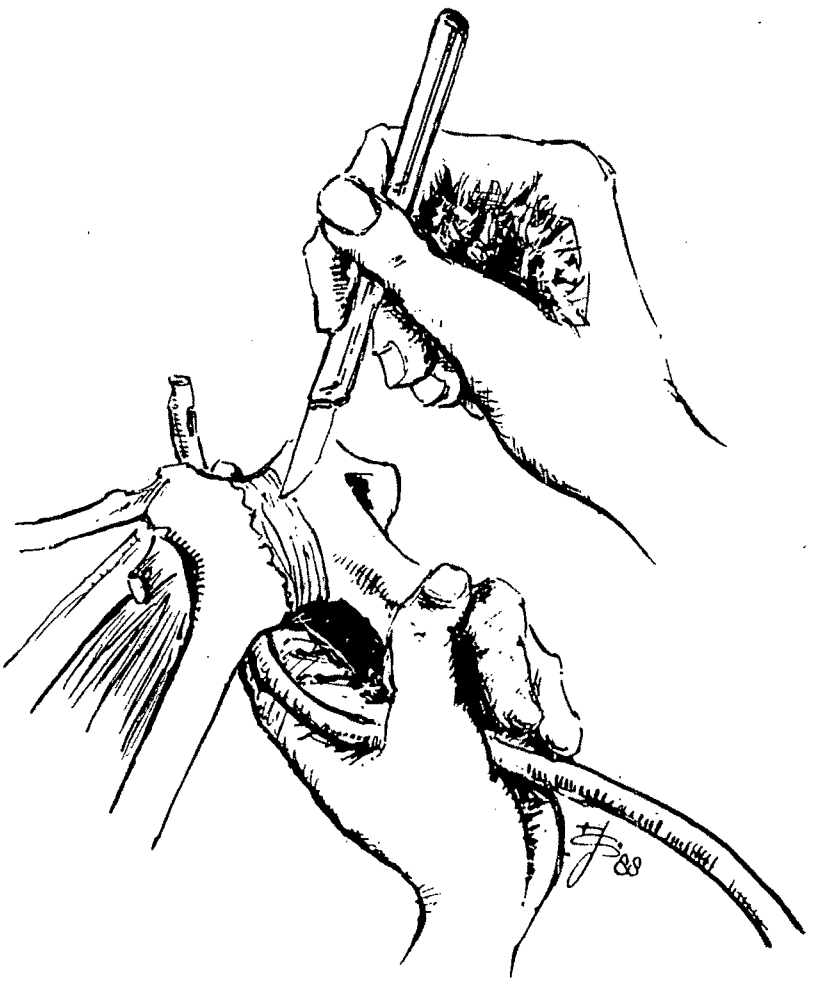

Fig. 1. Insertion of urinary catheter during procedure of symphysiotomy.

ternal morbidity included 30 vesicovaginal fistulas (1.7%), 33 lesions of the anterior vaginal wall including the urethra (1.9%), 10 cases of osteitis pubis–retropubic abscess (0.6%), 32 women with long-term walking difficulties or pain (1.8%), and 36 with stress incontinence (2.1%).[9] More than one complication often occurred in one woman. Therefore the number of women affected is less than the number of 141 complications (8.1%). Fifteen of the 30 fistulas appeared to be a result of pressure-necrosis of the bladder neck because of obstucted labor rather than because of symphysiotomy. The latter fistulas develop immediately after birth, whereas those that are a result of obstructed labor only develop some days after delivery when necrotic tissue is shed.

A previous symphysiotomy is said to cure cephalopelvic disproportion, and the outcome of subsequent labor in women with a history of previous symphysiotomy shows an 87% vaginal delivery rate. In only one study two cases of rupture of an unscarred uterus were reported after a previous symphysiotomy.[9]

It is not intended within the scope of this article to dwell on the technique of the procedure, which is explained in the existing literature.[10-11] However, a few remarks will be made here. The complication rate can be lowered by strict adherence to a protocol, and the rules provided by Gebbie[12] in 1974 are generally accepted. A symphysiotomy should be performed only when one third or more of the fetal head has entered the pelvic brim, the fetal head is not felt prominent in front of the symphysis, and cervical dilatation is >7 cm.

Second, some of the immediate fistulas or vaginal wall lacerations were a result of performing the procedure without the insertion of a urinary catheter; others were a result of the application of forceps after symphysiotomy. The insertion of a urinary catheter should never be omitted (Fig. 1) and the use of forceps is contraindicated. Instead, the vacuum extractor can be applied after symphysiotomy has been performed.[13]

Comparison of the results of symphysiotomy with those of cesarean section for cephalopelvic disproportion (the best possible control when randomization is

difficult) indicates less mortality risk for the mother, whereas maternal morbidity, although different in nature, does not differ much in frequency (Table II). The vaginal delivery rate after a previous symphysiotomy (87%) is much higher than that after cesarean section for disproportion (44%).[4] The need for blood transfusion with its risks related to acquired immunodeficiency syndrome is much less after symphysiotomy than after cesarean section.[14]

Comment

Symphysiotomy deserves a place in the management of cephalopelvic disproportion. The fact that symphysiotomy is not practiced at present in Western countries does not make this operation second-class or outdated in the greatly differing circumstances of Third World counties in which cesarean birth is generally disliked and carries great maternal risks of mortality and serious morbidity, especially when performed in advanced labor.[15-16] Two recent cases of symphysiotomy have been reported from Great Britain when there was unexpected pelvic entrapment of the aftercoming head of a breech infant.[17] In the American literature a recent plea was made for symphysiotomy in the management of serious shoulder dystocia.[18-19] However, in such emergency cases much expertise should be available to safely perform the procedure. This will seldom be the case.

But in selected cases of obstructed labor in developing countries, symphysiotomy is a relatively simple and rapid procedure to facilitate delivery, and can be regarded as an example of appropriate technology. It leaves the uterus unscarred and thereby diminishes the risk of future uterine rupture. Furthermore, it fulfills the sociocultural needs to achieve vaginal delivery in areas in which cesarean birth is a much disliked option, involving a woman's disgrace in failure to give birth in the normal way.[20] Fear of getting another cesarean section after a previous operation once caused a woman to abscond from the hospital. She died undelivered at home, possibly because of scar rupture.

From this review it is concluded that the adverse effects of symphysiotomy have been greatly exaggerated.[21-22] However, more research into the late sequelae of symphysiotomy should be undertaken in the rural areas of Third World countries. One such study is in progress in Zaire.[14]

The help of J. Stouten in drawing the figure is kindly acknowledged.

Cost-effectiveness of intrapartum screening and treatment for maternal group B streptococci colonization

Daniel M. Strickland, COL, USAF, MC, Edward R. Yeomans, MAJ, USAF, MC, and Gary D. V. Hankins, LT COL, USAF, MC

Lackland Air Force Base, Texas

Early-onset neonatal group B streptococci infection occurs in two cases per 1000 live births in the United States and is associated with a mortality rate >20%. Nearly 30% of infected infants have concomitant meningitis and half suffer permanent neurologic damage. Group B streptococci also account for at least 20% of postpartum metritis. The annual cost of group B streptococci infection in the United States is conservatively estimated at nearly 2000 neonatal deaths and >$500 million, excluding the costs of long-term neurologic handicaps. Intrapartum chemoprophylaxis with ampicillin is effective in curtailing transmission of group B streptococci from mother to infant. Methods have been developed to identify maternal colonization before delivery. We applied principles of decision analysis to evaluate cost-effectiveness of intrapartum screening for maternal group B streptococci colonization with various reported methods in cohorts of low- and high-risk women. In the United States intrapartum screening for group B streptococci is cost-effective and offers the potential to avert a significant number of neonatal deaths and postpartum infections. (AM J OBSTET GYNECOL 1990;163:4-8.)

Key words: Group B streptococcus, rapid screening, chemoprophylaxis, cost effectiveness

6/1/19579

Early-onset group B streptococci infections are a serious cause of morbidity and mortality in neonates, with an incidence of two to three cases per 1000 live births in the United States[1, 2] and a mortality rate of 20% to 30%.[2] It has been estimated that >2000 infants die from these infections each year in the United States. A survey of infants with neonatal sepsis found that group B

streptococci were the etiologic organisms in 41% of cases.[3] In terms of the economic impact of hospital treatment and the long-term management of neurologic sequelae, group B streptococci were the fourth most important cause of potentially preventable infectious morbidity in the United States.[2] The National Academy of Sciences has estimated that the cost of total disease from early-onset neonatal disease and obstetric disease exceeded $500 million in 1985.[2]

Numerous approaches to reduce the devastating toll exerted by these infections have been investigated, including immunotherapy and prophylactic antibiotics.[1] Three general methods of antibiotic prophylaxis against neonatal group B streptococci disease have been studied:

1. Antepartum treatment of pregnant women colonized with group B streptococci in the third trimester achieves a marked but transient reduction in colonization, but by term the colonization rate returns to pretreatment levels.[4] The high prevalence (up to 30% of pregnant women), the intermittent nature of the carrier state, and the high recurrence rate mitigate against cost-effectiveness of antepartum prophylaxis.[5]

2. Prophylactic treatment of all exposed neonates shortly after birth has produced mixed results.[6] In addition, infections with penicillin-resistant organisms increased among treated infants. Therefore routine use of penicillin prophylaxis is currently not recommended for exposed but asymptomatic neonates.

3. However, intrapartum treatment of colonized women has been shown to significantly and consistently reduce early-onset group B streptococci infections and mortality.[7-11] Two investigator groups[12, 13] have addressed the cost-effectiveness of such therapy—a consideration that is separable from the question of efficacy. These reports provide compelling arguments in favor of intrapartum prophylaxis, although the analysis of Boyer[12] was based on prenatal cultures as a means to predict colonization at presentation in labor, and Minkoff[13] proposed intrapartum cultures of only high-risk women. Both of these approaches may potentially overlook a significant number of parturients and neonates at greatest risk for group B streptococci disease. It is possible that these analyses may have underestimated the potential value of screening and prophylaxis.

Since the publication of these reports, several sensitive techniques have been developed to allow rapid detection of group B streptococci colonization.[14-18] Thus the potential exists to quickly and accurately identify women in labor who are colonized by group B streptococci and to initiate intrapartum antibiotic therapy in sufficient time to interdict neonatal, and possibly maternal, infections.

With the use of the methods of decision analysis we attempted to determine which populations of patients may benefit from intrapartum prophylaxis, how sensitive the analysis is to changes in test accuracy and costs of screening and treatment, and what the annual costs of such a program would be in the United States.

Table I. Baseline assumptions in the decision tree

Assumption	
Cost of screening test	$20[12]
Cost of treating colonized mothers	$200[12]
Cost of treating infected neonate	$22,000[12]
Probability of neonatal infection if mother colonized in labor	0.02[21-25]
Probability of neonatal death if infected	0.20[9, 21-25]

Material and methods

Decision analysis is a schematic process for examination of problems that require one or more decisions and that result in more than one outcome.[19] The analysis consists of four basic components: (1) the decision tree is a flow diagram that specifies alternative courses of actions and possible outcomes of these actions; (2) branch points in the decision tree are called chance nodes; an associated probability at each node is estimated from the medical literature; (3) relative values, expressed in units such as costs or deaths, are assigned to all outcomes; (4) the score for each decision alternative is calculated by multiplying the relative value for each outcome by the probability of its occurrence and adding relative value scores across all branches of the decision tree.

The decision tree used in this analysis is shown in Fig. 1. The baseline assumptions used in this analysis and the references from which the numbers were obtained are listed in Table I. Treatment of neonates born to colonized mothers was not considered separately in the cost analysis. However, the cost of antibiotic therapy referenced in Table I was taken from the study of Boyer,[12] the one group that continued prophylactic antibiotics into the neonatal period. Data from the other two groups would support not administering antibiotics to the neonates unless clinically indicated. A computer program written in QUICK BASIC computer language (Microsoft Corp., Redmond, Wash.) was used to calculate outcomes for various branch probabilities and relative values in the tree.

The performance parameters of test procedures reported to identify group B streptococci colonization are listed in Table II. Only those screening tests that allow detection in <2 hours were considered for this analysis.

Sensitivity analysis is a process in which the probabilities, relative values, or other parameters in a prob-

lem are varied to determine whether changes in them would affect the decision. In this case we determined the sensitivity of cost and survival to changes in the prevalence of colonization and the sensitivity and specificity of the screening test.

Results

The effects of intrapartum screening and treatment of group B streptococci colonization are shown in Table III. The effects on cost and survival ratios of varying test sensitivity and specificity are calculated for a range of prevalences. It is readily apparent that the extra costs of screening vary significantly with test sensitivity and specificity as well as colonization prevalence, although survival ratios depend only on test performance.

Survival ratios can exceed 1.0 even for relatively poor test parameters, although at low prevalences the average cost to avert one early neonatal death may be extremely high. For instance, with use of the procedure reported by Isada[15] in a population with a colonization rate of only 1% would require an average cost of $1.38 million to save one infant. However, in a cohort colonized at a rate of 20% the cost would be only $6700 per infant saved.

Comment

Screening is generally defined as "the presumptive identification of a disease or defect by the use of an examination or test procedure that can be applied rapidly, easily, and relatively inexpensively.[20] The goal of

screening is to identify persons who have a high likelihood of disease and thus require more diagnostic and usually more expensive confirmatory tests. However, in this analysis the result of the screening test determines which laboring women will be treated with prophylactic antibiotics. The sensitivity and specificity of the screening test incorporate the concept of confirmatory testing with a gold standard, although in a retrospective sense.

Confirmatory gold standards, such as intrapartum cultures are usually available too late to allow for prophylactic treatment. It was for this reason that we elected to consider only screening tests that could be obtained rapidly (<2 hours) and that could be obtained 24 hours a day in even small medical facilities.

From the analysis presented in Table III it appears that significant reduction in early-onset neonatal group B streptococci disease can be accomplished through intrapartum screening and chemoprophylaxis, even with the use of a test with less than optimum performance such as that reported by Isada.[15] However, unless the population at risk has a colonization prevalence >10%, the average cost to save one neonate may be exhorbitant. That determination involves many value judgments because it may be argued that the value of one life is inestimable.

With use of a very high-performance screening test such as reported by Brady et al.[16] invokes very few controversial value judgments. In the U.S. population as a whole, with a group B streptococci prevalence of 10% and a birth rate of 3.5 million, a screening and prophylaxis program with the test reported by Brady could avert 1230 neonatal deaths from group B streptococci annually at a total savings of $1100 per neonatal death averted. In a higher risk population such as women with preterm labor, premature rupture of the membranes, or intrapartum fever, the program could avert seven deaths and save an average of $216,000 for every 10,000 women in the cohort.

We have not considered the possible benefit from the reduction of the incidence of late-onset group B streptococci disease because data on the effectiveness of intrapartum antibiotics on this infection are sparse. Data that do exist but that were also not considered in our cost effectiveness analysis are savings that result from reduced maternal morbidity from group B streptococci and the reduction in costs of long-term neurologic sequelae from early-onset group B streptococci meningitis. These considerations would significantly increase the cost-effectiveness of screening and treatment.

Therefore we conclude that intrapartum screening for group B streptococci with a technique that allows for accurate and rapid ascertainment of colonization before intrapartum maternal chemoprophylaxis can effect a significant reduction in early-neonatal death from group B streptococci in a cost-effective manner. Although the evidence would support the screening of all laboring women in the United States, individual medical centers may use this analysis, applying their own cost estimates and colonization prevalences to de-

termine which cohorts of patients they believe should be screened and treated.

The effect of adjusting maternal serum α-fetoprotein levels for maternal weight in pregnancies with fetal open spina bifida

A United States collaborative study

A. Myron Johnson, MD, Glenn E. Palomaki, BS, and James E. Haddow, MD
Scarborough, Maine

The effect of adjustment of maternal serum α-fetoprotein levels for maternal weight was evaluated in 143 pregnancies associated with fetal open spina bifida. The cases were analyzed with gestational dates as initially assigned either by last menstrual period (73%) or by ultrasonography (27%). The weights of women with pregnancies affected by open spina bifida were found not to be different from unaffected pregnancies. Adjustment resulted in a net increase in detected cases at two commonly used cutoff points: 2.0 and 2.5 multiples of the median. At 2.0 multiples of the median, the detection rate increased from 80% to 84%, whereas at 2.5 multiples of the median the rate rose from 68% to 69%. Adjustment for maternal weight has previously been shown to reduce the false-positive rate in maternal serum α-fetoprotein screening for fetal open spina bifida by reducing variance in unaffected pregnancies; our data provide further support for consideration of maternal weight when interpreting maternal serum α-fetoprotein measurements. (Am J Obstet Gynecol 1990;163:9-11.)

Key words: Maternal weight, α-fetoprotein, open spina bifida

The adjustment of maternal serum α-fetoprotein (maternal serum AFP) levels for maternal weight is known to reduce the variance of distribution of maternal serum AFP levels in pregnancies not affected with fetal open spina bifida without shifting distribution in either direction.[1-3] If similar results were obtained in affected pregnancies, both sensitivity and specificity of maternal serum AFP screening would increase with maternal weight adjustment. This multicenter collaborative study examines for the first time the effect of maternal weight adjustment on a large series of pregnancies affected with fetal open spina bifida.

Methods

Study design. The study design is described elsewhere.[4] Participating centers were limited to those capable of complete ascertainment of pregnancies associated with fetal open spina bifida. Table I lists the participating centers, the number of pregnancies affected with fetal open spina bifida, and the collaborating investigators.

Maternal weight. This analysis was restricted to the 143 cases with reported maternal weights (10 black and 133 white women). In 118 of these, the multiple of the median values reported by the contributing centers had been adjusted for maternal weight. To standardize the analysis of the effect of maternal weight adjustment on the detection of open spina bifida, we first converted the adjusted multiples of the median values to unadjusted values according to each reporting center's own method.[5-7] Weight-adjusted multiples of the median were then calculated with the formula[8]:

$$\text{Weight-adjusted multiple of the median} = \text{Unadjusted multiple of the median} / 10^{(0.2658 - 0.00188 \times \text{Maternal weight in pounds})}$$

Gestational age. The initially assigned gestational age was used in the analysis and was based on last menstrual period in 107 cases and on ultrasonography in 36 cases. Dating by both methods was reported for 105 cases.

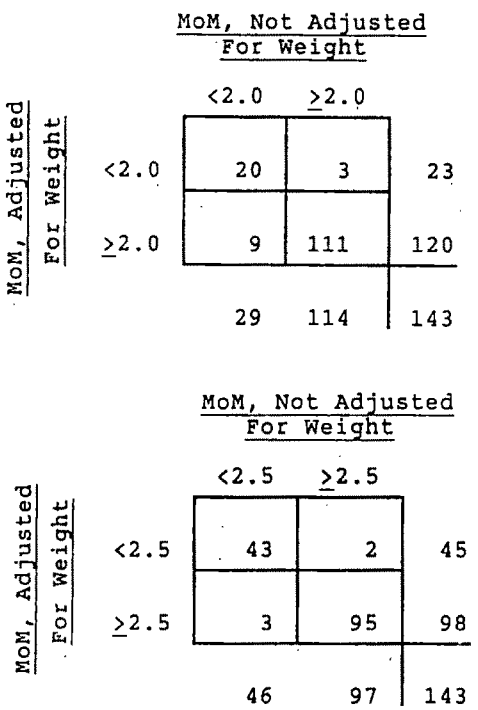

Fig. 1. Effect of adjusting maternal serum AFP for maternal weight on fetal open spina bifida detection at two commonly used cutoff points. This original method of gestational age assignment was based on last menstrual period in 107 cases and ultrasonography in 36. *MoM*, Multiples of the median.

Results

The median maternal serum AFP multiple of the median for the 143 affected pregnancies was 3.39 before weight adjustment and 3.41 after weight adjustment, and variance of the $\log_{10}$ transformed distribution was reduced by 0.0030 (from 0.0640 to 0.0610).

The effect of maternal weight adjustment on open spina bifida detection at two commonly used cutoffs, 2.0 and 2.5 multiples of the median, is shown in Fig. 1. Weight adjustment results in a net increase in detection of six cases with the 2.0 multiple of the median cutoff (three cases lost, but nine additional cases gained), raising the detection rate from 80% to 84%. With the 2.5 multiple of the median cutoff, there is a net increase of one case (two cases lost, but three additional cases gained) with weight adjustment, raising the detection rate from 68% to 69%. Similar slight increases or no overall changes in the detection rates are also obtained using the 128 cases with dating by last menstrual period or the 117 cases with dating by ultrasonography. In the former group, at a cutoff of 2.0 multiples of the median, the detection rate increases from 75% to 82% after weight adjustment, whereas the detection rate remains constant at 63% with the use of 2.5 multiples of the median as a cutoff. In the latter group, no overall changes occur in the detection rates of 90% and 80% for cutoffs of 2.0 and 2.5 multiples of the median, respectively. No combination of dating methods results in a net decrease in detection of open spina bifida after weight adjustment.

The median maternal weights in the pregnancies affected by open spina bifida are 140 pounds for white women and 147 pounds for black women, compared with approximately 139 and 149 pounds, respectively, in over 200,000 unaffected pregnancies collected from the three centers from which the largest number of cases (79) were obtained.

Comment

Maternal weight is known to influence maternal serum AFP levels in pregnancies not affected with open spina bifida, with larger women having lower levels, on average, presumably because of dilution into a larger plasma volume. When maternal weight is not taken into account, a larger proportion of lighter women and a smaller proportion of heavier women in the unaffected population will have positive high maternal serum AFP screening results. Adjusting maternal serum AFP values for maternal weight in pregnancies unaffected with fetal open spina bifida does not change the median but does reduce variance by 0.0026.[3] Consequently, the number of false-positive screening results is reduced.

One group has reported that the detection rate of fetal open spina bifida by maternal serum AFP screening is diminished by weight adjustment, but that study included only four patients, all of whom had positive maternal serum AFP screening results before the evaluation of weight adjustment.[9] Such a reduction in screening sensitivity might be expected if the population of women with open spina bifida–affected pregnancies weighed less than the unaffected population. A 1981 British study found a slightly lower average weight among affected pregnancies,[2] whereas an American study found a slightly higher average weight[10]; in neither of these studies was the difference statistically significant. The maternal weights in pregnancies with fetal open spina bifida in this study are not different from those in women with unaffected pregnancies in the United States.

This study demonstrates a 4% increase in the detection rate of open spina bifida after weight adjustment, with a maternal serum AFP cutoff of 2.0 multiples of the median, and a 1% increase with a 2.5 maternal serum AFP cutoff of 2.5 multiples of the median when gestational age dating is based on the initial assignment method. The advantage gained from adjustment decreases at the higher cutoffs, but in no case is the open spina bifida detection rate lowered. Thus a simple calculation can result in a slight increase in the detection rate for fetal open spina bifida while simultaneously reducing the false-positive rate.

Two-tier approach to biophysical assessment of the fetus

Martin S. Mills, MRCOG, David K. James, MD, and Sian Slade, RCM
Bristol, England

The biophysical profile score is widely accepted as a superior predictor of acute-on-chronic fetal asphyxia over the nonstress test. Nevertheless, in the United Kingdom facilities for assessment of high-risk pregnancies by nonstress test are more widely available than with the biophysical profile score. After a retrospective review of 2038 biophysical assessments in 500 high-risk pregnancies, it is suggested that biophysical evaluation of the fetus can be rationalized on the basis of the clinical problem and fetal growth. Terminal acute-on-chronic fetal asphyxia can be excluded by a two-tier method of fetal assessment by initial nonstress test backed up by the biophysical profile score when the nonstress test is suboptimal. (AM J OBSTET GYNECOL 1990;163:12-7.)

Key words: Fetus, biophysical profile, nonstress test, fetal asphyxia

The majority of pregnancies are uneventful, with delivery of a normal, healthy infant. However, there are a few pregnancies in which there is a risk of chronic fetal asphyxia; examples include pregnancies with reduced fetal movements, antepartum hemorrhage, a small-for-dates fetus, and maternal hypertension.

Methods used to assess antepartum fetal well-being have changed over the past 15 to 20 years. Whereas biochemical methods were popular in the 1970s, they have now been largely replaced by biophysical methods.[1] Such biophysical tests of fetal well-being include daily fetal movement counting,[2] nonstress cardiotocography,[3] contraction stress testing (CST),[4] and biophysical profile (BPP) evaluation.[5] The nonstress test (NST) is generally accepted as a useful method of fetal assessment and is the most widely used method in the United States and United Kingdom.[3] CST, never widely used in the United Kingdom, has declined in popularity in the United States. It is generally avoided before 34 weeks if there is a history of premature labor, third-trimester bleeding, multiple pregnancy, premature rupture of the membranes, or an incompetent cervix,[6] although persistent labor has not been reported after CST.[7]

Real-time ultrasonographic scanning enables dynamic assessments to be extended further in the form of a BPP.[8-11] In a prospective clinical study of 12,620 referred high-risk pregnancies, Manning et al.[12] showed that a fetal biophysical scoring system gives an accurate method for identification of the fetus at risk of perinatal death from acute-on-chronic fetal asphyxia. The false-negative and false-positive rates are considerably lower than those reported for the NST.[4]

The biophysical profile method of fetal assessment does have disadvantages. It is time-consuming in terms of hospital personnel and equipment. Furthermore, there may be considerable inconvenience incurred by the patient having to travel long distances for frequent hospital visits.

The aim of this study was to assess whether biophysical evaluation of fetal well-being could be rationalized.

Material and methods

Bristol Feto-Maternal Assessment Unit. The Bristol Feto-Maternal Assessment Unit[5] is run by a midwife trained in obstetric ultrasonography and a specialist in fetomaternal medicine. Patients referred for fetal assessment are managed in accordance with the following protocol.

Initial visit. A detailed ultrasonographic scan for normality and size is carried out. A BPP is performed; nonstress cardiotocography is done until two episodes of fetal heart accelerations of ≥15 beats/min and ≥15 seconds occurs; subsequently the four variables—fetal breathing, tone, movement, and amniotic fluid volume—are observed by means of real-time ultrasonography. The observation period lasts until a normal score is obtained (up to 30 minutes). The scoring system described by Manning et al.[13] is used. A score of 2 is assigned when the parameter is normal and 0 when it is abnormal.

A score of 8 or 10 in 30 minutes is interpreted as normal, indicating a nonasphyxiated fetus. An equivocal test result (score = 6) is repeated within 6 hours, and if the score is the same on subsequent testing, acute-on-chronic fetal asphyxia is suspected. A score of ≤4 is considered to be strongly suspicious of acute-on-chronic fetal asphyxia. The timing and mode of deliv-

ery are decided on the basis of fetal, obstetric, and maternal factors by the unit looking after the mother.

Subsequent visits. Biophysical profiles are carried out weekly, except in cases of severe intrauterine growth retardation, poorly controlled diabetes, or postmaturity (>42 weeks), where assessments are done twice weekly. Ultrasonographic measurements of fetal growth are repeated every 4 weeks in cases with normal growth but every 2 weeks in cases with abnormal growth. Abnormal growth is diagnosed when one or more of the following are recognized: Measurement of fetal abdominal circumference is below the 10th percentile; there is asymmetry of head and abdominal circumference values, there is decreasing fetal abdominal circumference growth trajectories crossing percentile lines.

Method. A retrospective analysis of 2038 BPPs from 500 pregnancies was undertaken. The NST for each BPP was analyzed and scored independently from the BPP as summarized in Table I. If the tracing was either of poor technical quality or abnormal with a score of ≤3, the NST was classified as "suboptimal." The evaluation was carried out by one of us (M. S. M.) without prior knowledge of infant outcome. Comparison of NST with BPP was undertaken according to fetal growth patterns, either (A) "normal growth," defined as abdominal circumference measurements following an expected growth trajectory above the 10th percentile, or (B) "abnormal growth," defined as abdominal circumference below the 10th percentile, or falling below the expected growth trajectory, or asymmetry of head and abdominal circumference values.

After the analysis of the NSTs and BPPs had been completed, the infant's outcome was recorded.

Table I. Scoring of NST

Variable	*Normal (score = 1)*	*Abnormal (score = 0)*
Baseline fetal heart rate (beats/min)	120-160	< 120, > 160
Short-term baseline varibility (beats/min)	≥ 5	< 5
Accelerations	≥ 2 Episodes of acceleration of ≥ 15 beats/min and ≥ 15 seconds' duration	< 2 Episodes of acceleration of < 15 beats/min and < 15 seconds' duration
Decelerations	Absent	Present ≥ 20 seconds and > 15 beats/min

Results

There were 514 deliveries (486 singletons and 14 twins). A total of 2038 biophysical profile scores were obtained (4.1 tests per patient; range 1 to 38). The commonest indications for referral were clinical suspicion of intrauterine growth retardation (39%), reduced fetal movements (17%), vaginal bleeding (15%) and hypertensive disease (14%). Other indications included previous stillbirth, diabetes mellitus, and multiple pregnancy. A total of 134 patients had more than one risk factor. The median gestational age at the time of referral was 34 weeks (range 24 to 44 weeks), and 62 (12%) patients were referred before 28 weeks.

The duration of real-time ultrasonographic observation was usually shorter than the maximum of 30 minutes; 1611 (79%) were completed in 10 minutes, 280 (14%) in 20 minutes, and 147 (7%) in 30 minutes.

Scores and outcomes. BPP and NST scores together with intrauterine and neonatal deaths are summarized in Table II according to fetal growth pattern. When the NST was not performed (48 cases), the gestation was often <28 weeks or the BPP score was normal ($n = 8$) without cardiotocography needed to add to the score. The majority of BPP scores were normal (98.4%). Where a test was equivocal (23 cases), it was repeated in 6 hours in 17 cases; 13 of these repeat tests were then normal. In no case did an abnormal BPP score (≤4) convert back to normal.

Relationship of NST and BPP. In 1561 cases (78.4%) there was a good correlation between the NST and BPP. A total of 423 NSTs (21.3%) were classified as suboptimal (score <4 or poor quality trace) and were followed by normal BPP scores.

In six cases the NST score was four and was associated with an equivocal BPP score of 6 (in no instance did a BPP score of ≤4 follow a NST score of 4). Among these six cases tests were repeated in five within 6 hours and BPP scores subsequently were normal (≥8). In these five cases fetal outcome was good with deliveries occurring between 1 and 6 weeks later. In the sixth case, at 40 weeks' gestation, with serial ultrasonography suggesting a symmetrically small fetus that was growing well, a BPP score of 6 was obtained after a normal NST score of 4. The BPP was repeated 1 hour later and a further score of 6 was obtained in 30 minutes. Labor was induced and a 2630 gm fetus was delivered vaginally 12 hours later. Apgar scores were 9 at 1 minute and 10 at 5 minutes.

In 26 cases the NST was suboptimal and the BPP score was equivocal or abnormal. Thirteen of these 26 cases with equivocal scores had normal scores when the assessment was repeated. Delivery was indicated in another eight cases for obstetric reasons (four cases) or because of a repeat abnormal score (four cases). The remaining five resulted in intrauterine or neonatal death and are discussed below.

Intrauterine and neonatal deaths. There were 10 intrauterine or neonatal deaths (Table III). This represents an uncorrected "reproductive loss rate" of 19.5

Table II. BPP and NST scores and baby deaths according to fetal growth pattern

Group	*Growth pattern**	*No. of mothers*	*No. of assessments*	*Optimal NST (4/4) and optimal BPP (≥8/10)*	*Suboptimal NST (<4/4) but optimal BPP (≥8/10)*	*Optimal NST (4/4) but suboptimal BPP (<8/10)*	*Suboptimal NST and BPP*	*NST not done*	*Intrauterine and infant deaths*

Case No.	*Intrauterine or neonatal death*	*Interval of assessment before death (days)*	*Gestation at delivery (wk)*	*Birth weight (gm)*	*NST score*	*BPP score and time taken*	*Indication for delivery and cause of death*	*Growth pattern (see text)*
1	Intrauterine	3	24	440	1/4	4/10, 30 min	Extreme IUGR	B
2	Intrauterine	1	25	465	Not done	6/10, 30 min	Retroplacental clot; spontaneous abortion	A
3	Intrauterine	1	25	134	1/4	2/10, 30 min	Severe IUGR; syndactyly; bilateral lung hypoplasia; bowel atresia; bilateral adrenal hypoplasia	B
4	Intrauterine	6	36	2100	1/4	6/10, 30 min	Hydropic fetus; amniocentesis showed trisomy 21; tetralogy of Fallot	A
5	Neonatal	2	38	1900	4/4	8/10, 10 min	Severe IUGR; dysmorphic fetus; chromosome abnormality (46,XX, + 22p)	B
6	Neonatal	1	33	835	2/4	8/10, 20 min	Severe IUGR; arrested growth; dysmorphic fetus; triploidy	B
7	Neonatal	3	39	4900	Not done	8/10, 10 min	Hydramnios; double-bubble and gut atresia diagnosed antenatally; inhalation of vomitus leading to respiratory failure after delivery	A
8	Neonatal	1	26	870	4/4	10/10, 5 min	Fulminating preeclampsia; cesarean section; gross prematurity	A
9	Neonatal	2	29	1520	4/4	10/10, 10 min	Premature rupture of membranes at 22 wk; premature labor and delivery; hypoplastic lungs; respiratory distress syndrome	A
10	Neonatal	1 hr	29	920	0/4	4/10, 30 min	Intrauterine growth retardation and evidence of fetal asphyxia; cesarean section; early neonatal death from gross asphyxia and prematurity; retroplacental clot	B

IUGR, Intrauterine growth retardation.

per 1000. Excluding abortuses (three cases) the gross (uncorrected) perinatal mortality rate was 13.70 per 1000 total births. The corrected perinatal mortality rate (excluding lethal abnormality and babies weighing <500 gm) of the group was 7.83 per 1000 births. There were no cases of stillbirth in a structurally normal fetus after a normal BPP score.

Abortuses. Three of the deaths occurred in utero at 24 to 25 weeks' gestation and were classified as abortions. Two of the deaths were due to asphyxia; both fetuses were growth-retarded and in addition there was placental separation in one case. The third abortus was dysmorphic.

Stillbirths. There was one intrauterine death after 26

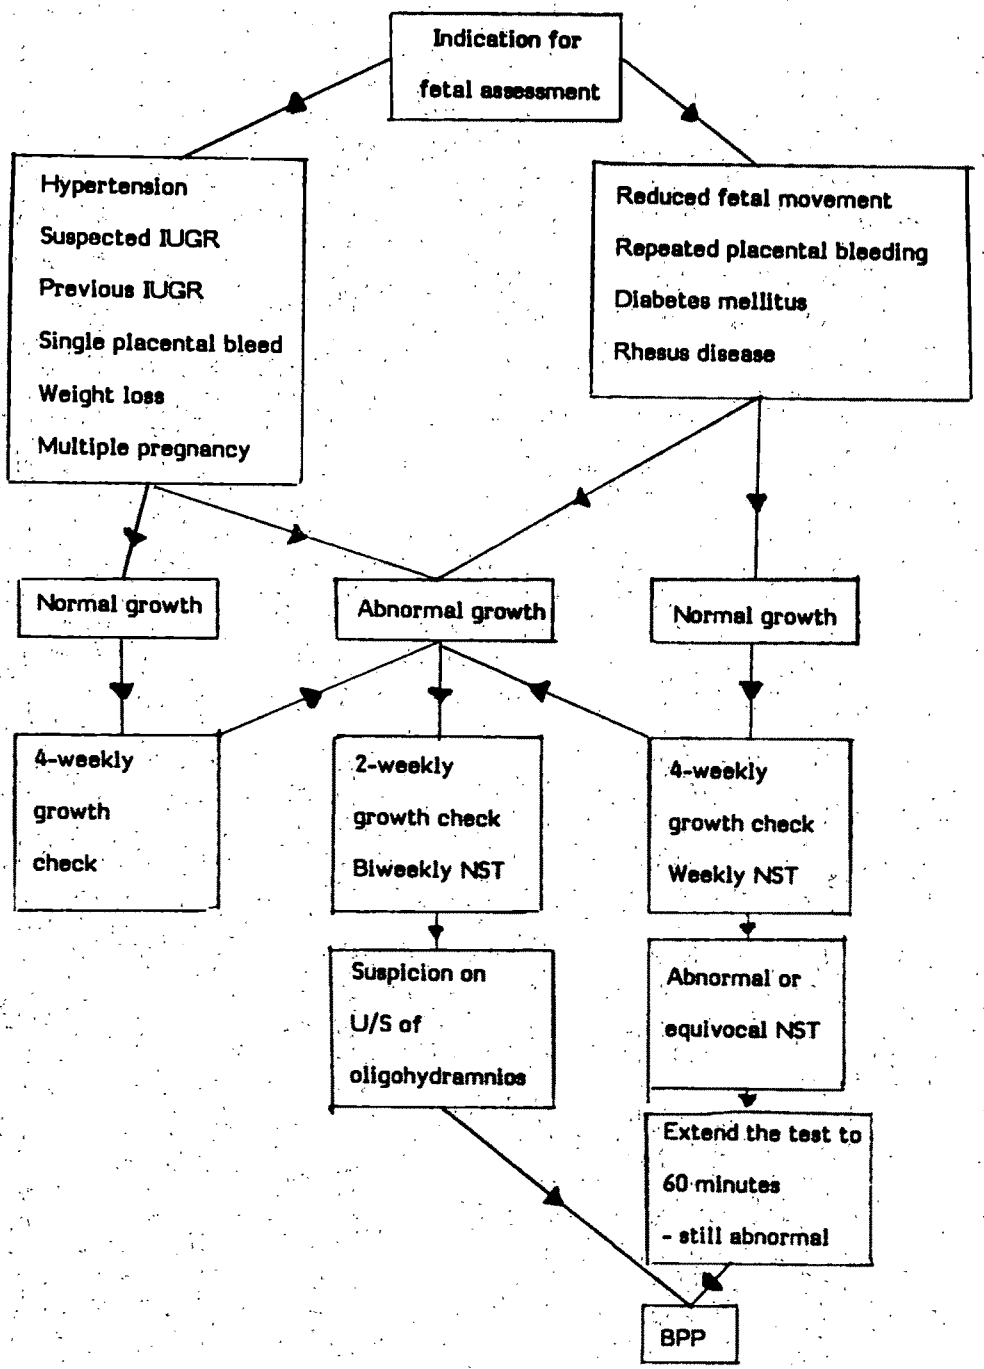

Fig. 1. Possible management protocol.

weeks, thus giving an uncorrected stillbirth rate of 1.96 per 1000 total births. This fetus was abnormal (hydrops fetalis with trisomy 21 and tetralogy of Fallot).

Neonatal deaths. There were six neonatal deaths, for an uncorrected neonatal death rate of 11.74 per 1000 births. Two infants had lethal abnormalities. Another had duodenal atresia; its postnatal management was suboptimal and it died of aspiration of vomitus. The remaining three deaths were as a result of extreme prematurity (gestations of 26 to 29 weeks). Only one had abnormal BPP and NST scores (4/10 in 30 minutes and 0/4) and was severely asphyxiated at birth.

Deaths caused by asphyxia. Three of the 10 intrauterine and neonatal deaths (two spontaneous abortions and 1 neonatal death) were due to asphyxia as outlined above. The sensitivity, specificity, and accuracy of an NST alone and a full BPP in predicting lethal fetal asphyxia are shown in Table IV.

Table IV. Accuracy of predicting lethal fetal asphyxia

	NST alone	*BPP*	
No. of tests	1990	2038	
Predicted			
Asphyxia	449	32	(9*)
No asphyxia	1541	2006	(2029*)
Developed			
Asphyxia	2†	3†	
No asphyxia	1988	2035

Specificity (%)	77.5	98.6	(99.7*)
False-positive (%)	99.6	90.6	(66.7*)
False-negative (%)	0	0	
Positive predictive power (%)	0.4	9.38	(33.3*)
Negative predictive power (%)	100	100	
Accuracy (%)	77.5	98.7	(98.7*)

*Value obtained on repeat testing where an equivocal BPP score of 6/10 was obtained.

†All predicted.

Comment

A number of biophysical tests exist that are used to assess fetal "health" or "well-being." The need for a critical view of many of these procedures has been emphasized.[14] The biophysical tests described in this paper (NST and BPP) are directed toward the detection of acute-on-chronic fetal asphyxia. Generally, they are better at confirming normality (high specificity and negative predictive power) than identifying abnormality (low sensitivity and positive predictive power). Furthermore, it is probable that the tests become abnormal relatively late in the chronic asphyxial process.

The experience of Manning et al.[12] shows that fetal biophysical scoring is an accurate method for identification of a fetus at risk of dying antepartum of asphyxia. They reported a false-negative rate of only 0.634 per 1000. This is similar to that reported for CST of 0.4 per 1000 with its potential risks and lower than that reported for the NST of 3.2 to 8 per 1000.[4, 15] Our report confirms that the BPP is superior to the NST in terms of a lower false-negative and false-positive rate. It is noteworthy that, despite theoretical limitations of the BPP from neurologic immaturity,[16] chronic fetal asphyxia was recognized with the BPP before 28 weeks in our study (Table III); this early diagnosis has been confirmed by others.[12]

However, the BPP does have the disadvantage of being a time-consuming process requiring specialist staff and frequent patient visits. Furthermore, fetal assessment with the NST is more widely available. According to our experience reported in this study, is there any way that the NST could be used safely as a first-level initial assessment in certain cases with the BPP used as a second-level subsequent assessment only in those cases where the NST is suboptimal?

In the majority of cases there was good correlation between normal NSTs and BPPs. There were no stillbirths after a NST score of 4 out of 4. In only six cases was a NST score of four out of four followed by an equivocal BPP score (6 of 10 in 30 minutes). Five of these were normal on retesting. One remained equivocal. The length of gestation was 40 weeks; labor was induced and a 2630 gm fetus was born in good condition after a 12-hour labor.

From this report we would suggest that biophysical assessment could be rationalized. After the initial biophysical assessment (including ultrasonographic screening for anomalies, fetal size, and liquor volume), further assessment of ultrasonographically normal fetuses could be determined on the basis of the clinical problem and whether the subsequent growth is normal (see Fig. 1). Where the clinical problem carries a risk of abnormal fetal growth (for example, hypertension, possible intrauterine growth retardation, weight loss, or multiple pregnancy), provided the growth (assessed every 4 weeks) is normal, then no further biophysical assessment is necessary. If the growth is abnormal, increasing the likelihood of acute-on-chronic asphyxia,[14] then biweekly NSTs and growth checks every 2 weeks should be undertaken. Where the clinical problem carries not only a risk of abnormal fetal growth but also of acute compromise without abnormal growth (for example, recurrent placental bleeding, reduced fetal movement, diabetes mellitus, or rhesus isoimmunization) then, in addition to growth checks, the NST also must be undertaken. This can be weekly if growth is normal and biweekly if abnormal. The BPP can be reserved for those cases where the NST is abnormal or equivocal or where there is a suspicion of oligohydramnios on ultrasonogram.

Using this approach we could reduce the workload of NSTs by >60% and BPPs by >75%. This latter figure could be improved further if the period of testing with equivocal NSTs was extended to 60 minutes since many suboptimal NST results in 30 minutes are merely a reflection of the periodic nature of fetal behavior. An antepartum NST is far more widely available than biophysical scoring; furthermore, fetal heart rate monitoring could be undertaken by the mother herself using the telephone[17, 18] and could reduce the demands on hospital and community staff even more.

Sinusoidal fetal heart rate pattern during cardiopulmonary bypass

Ann B. Burke, MD,[a] Dongzin Hur, MD,[b] Jean C. Bolan, MD,[a] Paul Corso, MD,[c] and Fernando G. Resano, MD[b]

Washington, D.C.

A gravida 3, para 2 woman underwent an emergency mitral valve replacement at 24 weeks' gestation. A sinusoidal fetal heart pattern was recorded throughout cardiopulmonary bypass. This pattern persisted despite a pump flow maintained at 31 ml/m^2 min and an intravenous infusion of phenylephrine to maintain the mean systemic arterial pressure at 50 mm Hg. (AM J OBSTET GYNECOL 1990;163:17-8.)

Key words: Fetal heart rate, cardiopulmonary bypass, pregnancy, general anesthesia

Infective endocarditis associated with congestive heart failure and systemic embolization has a grave prognosis that may be modified only by a valve replacement. This situation is rare in pregnancy. Emergency open heart surgery during pregnancy may not carry a higher risk for the patient, but the risk to the fetus is great. With advances in the management of these cases, particularly with fetal monitoring, the fetal mortality rate may be as low as 9.5%, as shown in a recent report.[1]

6/1/20101

We monitored a patient who underwent emergency mitral valve replacement at 24 weeks' gestation because of infective endocarditis. We recorded a sinusoidal pattern during the cardiopulmonary bypass. This type of fetal heart rate pattern has not previously been reported in association with surgery during pregnancy.

Case report

A 32-year old woman, gravida 3, para 2, was admitted to our hospital at 24 weeks' gestation because of *Streptococcus viridans* endocarditis that had resulted in mitral regurgitation with congestive heart failure refractory to medical treatment. She had a right cerebrovascular accident before her transfer to our institution. Medical history was significant for a dental procedure approximately 6 weeks before this admission. No antibiotic

prophylaxis was used since she was not known to have mitral valve prolapse. Despite intensive medical management, the congestive heart failure worsened and replacement of the mitral valve was recommended. After insertion of a pulmonary artery catheter and with left uterine displacement, external fetal heart rate monitoring with a model 8030A Hewlett-Packard cardiotocograph was begun. The initial recording showed a normal fetal heart rate with good variability. After induction of anesthesia with intravenous diazepam and sufentanil, a gradual loss of beat-to-beat variability of the fetal heart rate was observed. After the initiation of cardiopulmonary bypass, a persistent sinusoidal pattern with a rate of 120 to 150 beats/min was observed. Although the pump flow was maintained at 31 ml/m²/min, mean arterial pressure was 25 to 30 mm Hg. Phenylephrine, an α-adrenergic receptor agonist, was infused intravenously to raise the mean arterial pressure to 50 mm Hg. It did not alter the existing sinusoidal fetal heart rate pattern. Rectal temperature was maintained at 37° C. On completion of the valve replacement, the patient was weaned from cardiopulmonary bypass. Intravenous infusions of dopamine and isoproterenol were required to maintain a cardiac index of 31/m²/min. The fetal heart rate returned to the prebypass pattern with a continued decreased beat-to-beat variability. Normal variability did not return until several hours after operation. The patient was monitored with serial ultrasonography. Biophysical profile measurements were started at 28 weeks' gestation and increased to twice weekly at 34 weeks' gestation. At 39 weeks' gestation labor was induced because of poor fundal growth and suspected intrauterine growth retardation. A healthy female infant weighing 2885 gm was delivered with Apgar scores of 9 and 9 at 1 and 5 minutes, respectively. A postpartum tubal ligation was performed. The child has been followed up for 2 years and her developmental status is normal.

Comment

The fetal hazards during open heart surgery appear multiple but their precise mechanisms are undetermined. Fetal distress may occur because of low uterine blood flow, uterine artery spasm, particulate or bubble emboli, and sludging of blood, which may interfere with placental circulation.

Persistent fetal bradycardia and fetal bradycardia with late deceleration patterns have been reported during cardiopulmonary bypass.[2] Temporary improvement may occur with an increase of flow rate; however, fetal heart rate usually deteriorates again to persistent bradycardia with prolonged bypass.

In our patient a persistent sinusoidal fetal heart rate pattern was recorded. It may have reflected fetal acidosis, despite a perfusion flow rate of 31 ml/m²/min. Since uterine perfusion is dependent on perfusion pressure, mean arterial pressures of 70 mm Hg have been recommended. An α-adrenergic receptor agonist, phenylephrine, was infused with no changes in the fetal heart rate pattern. One might therefore conclude that the perfusion flow rate is more important than perfusion pressure for maintaining uterine blood flow during cardiopulmonary bypass.

In summary, a persistent sinusoidal heart rate pattern was recorded during a normothermic, high-flow, cardiopulmonary bypass. Increasing the systemic vascular resistance with an α-adrenergic receptor agonist did not restore the fetal heart rate to the prebypass pattern. More studies and experience are needed to learn the effect of nonpulsatile cardiopulmonary bypass on uterine and umbilical circulations.

Risk factors for perinatal group B streptococcal disease after amniotic fluid colonization

Helayne M. Silver, MD, Ronald S. Gibbs, MD, Barry M. Gray, MD, and Hugh C. Dillon, MD†

San Antonio, Texas, and Birmingham, Alabama

A group of 1031 parturient women at high risk for intraamniotic infection were studied. Women in whom group B streptococci grew from cultures of the amniotic fluid did not differ in clinical risk factors when compared with similar parturient women without group B streptococcal colonization of amniotic fluid. Patients who had perinatal group B streptococcal disease (maternal or neonatal bacteremia) did not differ from those without disease, by maternal or neonatal acute antibody levels or antibody response, inoculum size, or serotype of the colonizing strain. (AM J OBSTET GYNECOL 1990;163:19-25.)

Key words: Group B streptococci, intraamniotic colonization

Many studies have assessed risk factors for perinatal group B streptococcal disease, yet our understanding is incomplete. The goal of this investigation was to assess clinical and selected laboratory risk factors for group B streptococcal maternal infection and early-onset neonatal sepsis in a well-defined, high-risk population. Because most early-onset neonatal infections begin in utero, we were especially interested in determining the role of amniotic fluid colonization, amniotic fluid inoculum size, maternal antibody level, maternal antibody response, and maternal clinical characteristics that might help predict the risk for perinatal disease.

Methods

Patient population. Patients were predominantly indigent and of Mexican-American extraction, delivered at Medical Center Hospital, San Antonio, Texas, between July 1979 and December 1987. Patients selected for study included parturient women with clinically diagnosed intraamniotic infection and asymptomatic women with duration of ruptured membranes >10 hours.

Clinical data. Data were collected prospectively from maternal and neonatal hospital charts and included 25 clinical risk factors or outcome variables. Patients were divided into four categories, according to the clinical diagnosis. (1) There were 467 patients with intraamniotic infection defined on the basis of an oral temperature >37.8° C plus two or more of the following: maternal tachycardia (>100 beats/min), fetal tachycardia (>160 beats/min), uterine tenderness, foul odor of the amniotic fluid, or peripheral leukocytosis (>12,000/mm³). (2) There were 99 patients with endometritis, defined as a postpartum oral temperature >37.8° C with localized uterine tenderness. (3) There were 124 patients with fever only, defined as a transient temperature elevation to >37.8° C without localizing signs and not receiving therapeutic or prophylactic antibiotics. (4) There were 341 asymptomatic parturient women with temperature <37.8° C, who had rupture of membranes >10 hours and received no therapeutic antibiotics. Maternal sepsis was diagnosed on the basis of clinical suspicion and confirmed by a positive blood culture. Neonatal sepsis was suspected in infants whose mothers had a clinical diagnosis of intraamniotic infection, in preterm infants with rupture of membranes >24 hours, or in infants with clinical signs of sepsis. Neonatal sepsis was confirmed by isolation of a pathogenic organism from the blood. Neonatal pneumonia was defined as respiratory symptoms with a patchy infiltrate on chest x-ray film. Therapeutic antibiotics were used in cases of suspected sepsis pending culture results but were discontinued if sepsis was not confirmed. Infants were treated according to clinical indications and not solely on the basis of an amniotic fluid culture that was positive for group B streptococci.

Microbiologic data. Patients were further classified by the presence or absence of group B streptococci in amniotic fluid. Amniotic fluid was obtained from all patients by aspiration of an intrauterine pressure catheter that had been inserted for obstetric indications. In

those patients with a clinical diagnosis of intraamniotic infection, the specimen was collected before the administration of antibiotics. To minimize the possibility of contamination, the first 7 ml (equivalent to the volume of the catheter) was discarded, and the next 5 to 20 ml was collected in a separate plastic syringe. Collection of vaginal swabs during labor began in March 1986. Collection of neonatal surface cultures began in January 1986. Neonatal cultures were obtained from the external auditory canal and throat, in the delivery room when possible but always within 24 hours of birth. All amniotic fluid specimens were transported to the laboratory and plated quantitatively within 60 minutes. All specimens were plated on a variety of media for aerobes and anaerobes.[1] Beginning in January 1986, specimens were also cultured in selective media for group B streptococci consisting of Todd-Hewitt broth with 8 mg/L gentamicin and 15 mg/L nalidixic acid. Maternal and neonatal blood cultures were obtained when clinically indicated with the use of two 100 ml bottles containing trypticase soy broth with 3% carbon dioxide and 0.03% sodium polyanethol sulfate (BBL, Cockeysville, Md.). Isolates were identified by standard techniques. Group B streptococci isolates were serotyped by previously reported methods.[2]

Serologic data. Maternal and neonatal blood was collected within 48 hours of delivery and at 4 to 6 weeks post partum from available patients. Sera were stored at −70° C until assayed. Quantitative determinations for total antibody specific for the polysaccharide antigens of group B streptococcal types Ia, Ib, II, and III were performed by an enzyme-linked immunosorbent assay[3] adapted for use with plastic microwells.[4] A peroxidase-labeled antihuman immunoglobulin second antibody was used that detected antibodies of all classes. Results were expressed as micrograms of antibody protein per milliliter.[3, 4] Serologic response in paired sera was assessed by the mean difference of antibody levels in sera from convalescent and acute conditions. Amniotic fluid antibody levels were determined[4] in a small group of patients.

Statistical methods. Discrete clinical data were analyzed across all diagnostic categories and within each by χ^2 goodness of fit test or by Fisher's exact test, where appropriate. Continuous data were analyzed (1) within each diagnostic category by two-tailed Student's *t* test, (2) across all diagnostic categories by two-way analysis of variance with the presence or absence of group B streptococci and diagnoses as the main effects, and (3) within each group B streptococcal culture status group by the Student–Newman-Keuls procedure. Serologic data were analyzed by two-tailed Student's *t* test.

Results

Clinical risk factors. A total of 1031 patients were enrolled in the study. One hundred thirty-three (12.9%) patients had positive cultures for group B streptococci in the amniotic fluid (group 1). The remaining 898 patients formed group 2. The clinical diagnoses by amniotic fluid group B streptococcal culture status are shown in Table I. When group B streptococci were present in the amniotic fluid, significant clinical risk factors by analysis of covariance included a longer duration of internal monitoring (12.9 ± 7.0 vs 10.9 ± 6.1 hours, $p = 0.003$) and a slightly, but significantly higher temperature post partum (37.9° ± 0.7° C vs 37.2° ± 0.7° C, $p = 0.028$). All other clinical risk factors and variables, including duration of labor, maximum temperature in labor, and number of vaginal examinations, were indistinguishable by amniotic fluid group B streptococcal culture status.

Neonatal diagnoses by amniotic fluid group B streptococcal culture status are shown in Table II. The rate of culture-confirmed neonatal group B streptococcal sepsis in infants of mothers with group B streptococci

from cultures of the amniotic fluid was 7 of 133 (5.3%). We compared clinical risk factors of group I mothers whose babies had group B streptococcal sepsis with those of mothers whose infants did not. There was a significantly higher maximum postpartum temperature in the mothers of septic infants (38.5° ± 1.0° C vs 37.9° ± 0.7° C, $p = 0.045$) but no other significant differences in clinical risk factors.

Transmission of group B streptococci. Group B streptococci were identified in 20% (42/212) of vaginal cultures. When group B streptococci were detected in the vagina, they were also cultured from the amniotic fluid in 81% (34/42). There were no differences in the clinical factors between those patients without transmission of group B streptococci from the vagina to the amniotic fluid and the 34 patients with transmission. In 12% of cases (4/34), group B streptococci were recovered from amniotic fluid but not from the vagina. When group B streptococci were cultured from the amniotic fluid, 76% (22/29) of the corresponding neonates with cultures for group B streptococci were colonized. There was no difference in the rate of neonatal colonization whether the mother did or did not receive therapeutic antibiotics (usually penicillin or ampicillin plus gentamicin) before delivery (4/6 or 67% vs 16/21 or 76%, $p = 0.5$).

Serologic results. Paired sera from acute and convalescent conditions were available from 28 mothers and 13 babies who had group B streptococci recovered from the amniotic fluid. Acute sera only were available from an additional two mothers and three babies. The isolate from one patient could not be typed. Seven mothers were colonized with Ia (23%), 10 with Ib (33%), five with II (17%), and seven with III (23%). Antibodies to all four serotypes were assessed in each subject. To evaluate the specific serologic response, we compared the individual's antibody response to the serotype that was isolated from the amniotic fluid (homologous) with the antibody response to the three serotypes that were not isolated (nonhomologous) as a background control. Mean maternal acute type-specific homologous antibody levels are compared with mean nonhomologous antibody levels in Table III. There were no significant differences in antibody levels. Table IV compares the antibody response, as assessed by mean convalescent minus mean acute antibody levels for type-specific homologous and nonhomologous serotypes. There were no significant differences. Mean maternal acute type-

specific homologous antibody levels in patients with either maternal or neonatal bacteremias (five maternal and four neonatal) are shown in Table V. The distribution of serotypes in cases of bacteremia is similar to that of cases without bacteremia. Maternal antibody response in patients with either maternal or neonatal bacteremias is shown in Table VI. There are no significantly different results by this analysis, although numbers are small and the standard deviations are large.

Neonatal acute antibody levels varied from 4% to 46% of maternal levels for type-specific antibody and 3% to 19% of maternal levels for nonhomologous antibody. The mean changes in type-specific homologous and nonhomologous antibodies in neonates are shown in Table VII. The rise in type Ia homologous antibody is significantly higher than the rise in nonhomologous type Ia antibody. In all cases serotypes of the group B streptococcal isolates from the neonates were concordant with the isolates from their mothers.

Antibody levels were assayed in 50 amniotic fluid specimens. Mean levels in amniotic fluid were 0.04 ± 0.10 μg/ml for type Ia, 0.20 ± 0.13 μg/ml for type Ib, 0.05 ± 0.05 μg/ml for type II, and 0.14 ± 0.13 μg/ml for type III. These levels were 2% to 4% of those in paired acute maternal sera. For paired amniotic fluid and serum, the Pearson correlation coefficient was low, indicating no linear relationship. Similarly, there were no apparent nonlinear relationships.

Inoculum size. There was no significant relationship between quantitative amniotic group B streptococcal cultures and neonatal outcome. For example, 10 of 12 (83%) mothers of babies with group B streptococcal sepsis or pneumonia had group B streptococcal colony counts of >100,000/ml versus 86 of 120 (72%) well babies.

Comment

Several strategies to reduce the risk of early neonatal group B streptococcal sepsis have been attempted with variable success. Attempts to eliminate the carrier state in antepartum patients have uniformly failed,[5-7] probably because antibiotics only suppress the bacteria and mothers may become recolonized from the lower gastrointestinal tract or by sexual transmission.[8] Neonatal penicillin prophylaxis also has proved unsuccessful, as most neonates with early-onset sepsis already have bacteremia at birth.[9, 10] The most successful approach has been selective intrapartum therapy of group B streptococcal carriers with known risk factors for neonatal group B streptococcal sepsis (prematurity, prolonged duration of membrane rupture, and intrapartum fever).[11-14] One difficulty with this approach is that, in patients whose sole risk factor is fever in labor, therapy may begin too late to prevent disease. Boyer and Gotoff[13] found that with intrapartum therapy there were no cases of neonatal sepsis in patients at risk. However, in six of 23 patients with fever as the

sole risk factor, the infants were still colonized with group B streptococci.[14] This is in agreement with our finding that intrapartum therapy after intraamniotic infection was clinically evident did not decrease the rate of vertical transmission of group B streptococci to the neonate from the amniotic fluid. Another drawback of the approach by Boyer and Gotoff is it requires antepartum screening for group B streptococcal carriers. This poses a major logistic problem for many obstetric services, especially where a large population of patients may have late prenatal care or none. Rapid diagnostic tests have not been demonstrated to be sensitive or specific enough to be clinically useful.[15]

A major difficulty in designing an effective prophylaxis protocol has been incomplete understanding of the pathophysiologic features of group B streptococcal perinatal disease. There are at least three basic mechanisms by which a colonizing organism can become a disease-producing organism: an overwhelming inoculum, a compromised host, or a highly virulent strain. Most studies have examined a hypothesis concerning one of the potential mechanisms. We felt that by examining multiple potential mechanisms in a group of well-defined patients with known risk factors we could relate the roles of the selected variables. Since colonization of the uterine cavity is presumably the first step to invasive perinatal disease, the ideal group for comparison would be patients with vaginal group B streptococcal colonization without amniotic fluid colonization. However, there were only eight patients in this group. We therefore compared patients with and without group B streptococci in the amniotic fluid.

We examined the role of the inoculum by several approaches. We quantitated the inoculum in amniotic fluid and found we could not differentiate infants with sepsis from well infants by the colony count of group B streptococci in the amniotic fluid. The first step in development of invasive disease is colonization. We found that group B streptococci were transmitted vertically to the fetus in 76% of cases when the organism was present in the amniotic fluid. In eight reports where transmission from a colonized vagina to the neonate was examined, the mean transmission rate was 46% with a range of 34% to 72%.[10, 13, 16-21] Our patients were selected by the presence of membrane rupture >10 hours or intraamniotic infection. Therefore it is possible that all of our patients had unusually large lower genital tract colony counts and that the mere presence of group B streptococci in the amniotic fluid implies a large vaginal inoculum. In fact, in our patients 89% of group B streptococcal vaginal carriers had group B streptococci in the amniotic fluid while in labor. It is not possible to determine whether this is a usual occurrence or simply related to the method of patient selection. Boyer reported a group B streptococcal neonatal sepsis rate of 0.6 in 100 term patients with vaginal colonization[12] in contrast to our rate of 5 of 100 term patients with amniotic fluid colonization. Another factor reported to increase the risk of neonatal sepsis is prolonged duration of membrane rupture, which presumably increases inoculum size in amniotic fluid. In Boyer's studies a duration of membrane rupture of >18 hours increased the risk sevenfold.[11] Although the duration of membrane rupture does not distinguish the neonatal sepsis cases in our study, the long mean duration of rupture of membranes may explain the excess of cases of neonatal sepsis compared with those in previously reported series.

Anthony et al.[22] noted that 36% of women are chronic carriers of group B streptococci and that on serial culturing the vaginal cultures will consistently be positive for group B streptococci. Twenty percent of women will be transient carriers with only one positive culture, followed and preceded by negative cultures, while another 15% will be intermediate carriers, with several transient episodes. The remaining 29% of patients did not fit into any of these categories. Others[23] have noted that mothers delivered of infants with group B streptococcal sepsis are chronic carriers of group B streptococci. This suggests a host deficiency, and there has been much interest in whether these mothers can be distinguished by a lack of protective antibody level or

a deficient antibody response. A level of 2 μg/ml[24] of immunoglobulin G has been used to designate "protective" antibody status. Because absolute antibody levels are not well standardized from one laboratory to another, we chose not to define an arbitrary level of protective antibody but to compare acute antibody levels between clinically defined groups of patients.

Previous investigators have reported a lower acute antibody level in mothers with sepsis or mothers of infants with sepsis compared with asymptomatic colonized mothers with asymptomatic infants.[25-27] We could not confirm these findings. In addition, mothers of septic infants have been reported to be poor antibody responders when compared with mothers of well infants.[25, 26, 28] Our results show that the acute antibody levels are not significantly different and antibody response in mothers with bacteremia is not significantly different from that of women without bacteremia. Mean acute homologous antibody levels were higher in types Ia and III but lower in types Ib and II. We suspect there is no real difference. We note that the mean change in homologous antibody was substantially greater for serotypes Ia, Ib, and III. Because of the small sample size, there may have been real, but undetected, larger rises in antibody in cases of bacteremia.

Prematurity is a major risk factor for group B streptococcal sepsis. It has been postulated that these infants are more vulnerable because of relative lack of passive protection from transplacental immunoglobulin G when they are born before 32 weeks. In our study six of seven infants with group B streptococcal sepsis were term infants, but so were infants of approximately 90% of the pregnancies studied. Acute antibody levels in the seven mothers delivered of these infants were comparable to those of the other mothers. Unfortunately, because serologic data were available in only one infant, we cannot comment on the role of passive antibody transfer.

The third factor potentially leading to the development of invasive disease is that of strain virulence. It has been suggested that serotype III is the most virulent, causing >90% of late-onset neonatal disease and up to 80% of early-onset disease.[9, 29] In contrast, in 14 studies type III represents ony a mean of 40% of serotypes in asymptomatic vaginally colonized women.[5-9, 12, 17-19, 21, 30-33] The distribution of serotypes in our patients is consistent with that reported in the latter studies. It therefore does not appear that some serotypes are more likely to ascend to the uterine cavity from the vagina during labor.

In this group of high-risk patients, we were unable to distinguish mothers delivered of infants with sepsis by inoculum size, serum or amniotic fluid antibody status, or serotype. The rate of neonatal group B streptococcal sepsis is unusually high in this group of patients. It is possible that by selecting a group with prolonged membrane rupture or clinically evident intraamniotic infection we are obscuring the role of inoculum size. The role of protective maternal antibody appears to be minimal. The commonly used method of characterizing strain virulence by serotype is probably an oversimplification. The role of strain virulence deserves more investigation.

The current strategy is intrapartum therapy of patients at high risk because of prolonged membrane rupture or fever. Our study suggests this may be too late for a significant number of patients. Until we have a better understanding of the mechanism of transition from asymptomatic colonization to infection with group B streptococci, our attempts at prophylaxis are hampered.

Blood flow velocity and pulsatile diameter changes in the fetal descending aorta: A longitudinal study

Håkan Stale, MD, Gerhard Gennser, MD, PhD, and Karel Maršál, MD, PhD
Malmö, Sweden

Blood flow velocity and pulsatile diameter changes in the fetal descending aorta were measured subsequently with pulsed Doppler ultrasonography and phase-locked echo-tracking technique, respectively. Blood flow velocity and pulse-wave curves wih equal beat-to-beat intervals were synchronized by external fetal electrocardiogram. The systolic increase in blood flow velocity and in vessel diameter started simultaneously. The velocity peak preceded the diameter peak by a significant margin (p in the range 0.0001 to 0.0014). The time interval was more pronounced in the thoracic than in the abdominal part of the aorta and was slightly smaller near term. The effective diameter, calculated from the synchronized integrals of the blood flow velocity and the diameter curves, was significantly greater (p in the range 0.0001 to 0.0016) than the mean diameter. The difference tended to decrease with advancing gestational age and was more pronounced in the thoracic than in the abdominal aorta. The maximum error incurred by the use of nonsimultaneous measurements of blood flow velocity and vessel diameter when calculating volume blood flow was found to be <8% and thus probably of little practical importance. (Am J Obstet Gynecol 1990;163:26-9.)

Key words: Aortic diameter, blood flow, fetal, ultrasonography

The noninvasive method to measure blood flow velocity in the fetal aorta by application of combined real-time and pulsed Doppler ultrasonographic techniques[1] has become an important contribution to the surveillance of fetal circulation in utero. However, the estimation of volume blood flow, calculated from the time-averaged mean blood flow velocity and the vessel diameter, is not particularly accurate.[2, 3] One of the main sources of error is the impossibility of simultaneous measurement of the blood flow velocity and the diameter of the vessel because of ultrasonographic interference. Usually the mean of 10 static measurements of the diameter from real-time images has been taken as a value representative for the average caliber and included in the calculation of volume blood flow.[4] Furthermore, the time lag between the pulsatile courses of velocity and pressure[5] and that of the diameter has not been taken into consideration. The possible influence of these factors on the calculation of volume blood flow in the thoracic aorta of term fetuses has been presented and discussed in earlier studies that used fetal electrocardiogram (ECG) for the synchronization of the mean blood flow velocity and diameter curves.[6, 7] To investigate these questions further and to analyze the possible effects of gestational age, a longitudinal study was performed with measurements at two different sites on the fetal descending aorta.

Material and methods

To measure the fetal aortic blood flow velocity a combination of a 2 MHz pulsed Doppler instrument (Alfred, Vingmed, Horten, Norway) and a 3 MHz real-time linear array scanner (ADR, Tempe, Ariz.) were used.[2] The fetal aorta was localized in a longitudinal section with the real-time transducer held parallel to the vessel. The Doppler transducer was attached to the real-time transducer at a fixed angle of 45°, thereby enabling correction of the measured blood flow velocity for the angle. The Doppler shift signals were analyzed on-line by a spectrum analyzer (Daisy, Vingmed, Horten, Norway). Maximum and mean blood flow velocity were estimated automatically on-line and the analog signals of the mean velocity were stored on magnetic tape simultaneously with the fetal ECG signals and were played back later on a chart recorder.

The pulsatile changes in the fetal aortic diameter were recorded with an electronic phase-locked echo-tracking instrument (Diamove, Teltec, Lund, Sweden) built into the real-time ultrasonography scanner.[8] The spatial resolution of the system was 14 μm at 1.28 kHz repetition frequency. The electronic markers of the tracking gate were locked to the inner surface of the opposite vessel walls in the longitudinally visualized fetal aorta, the diameter thereby was measured continuously in a plane perpendicular to the longitudinal axis

of the vessel. The analog output signals were stored on magnetic tape simultaneously with the fetal ECG signals and then were played back later on a chart recorder.

The blood flow velocity and the aortic diameter were measured subsequently with as short a time interval as possible. A switch was used to alternate between the Doppler instrument and the real-time scanner. All recordings were performed during periods of fetal quiescence without breathing or gross movements.

External fetal ECG was obtained with a custom-made electrocardiograph,[9] producing signals sufficient to define fetal QRS complexes. These complexes were used to select equal beat-to-beat intervals (maximum interbeat difference permitted, <5%). This was essential for the synchronization of individual mean blood flow velocity and aortic diameter curves of similar pulse duration. For each fetal measurement, velocity and diameter curves from 10 equal cardiac cycles were fed into a microcomputer with a digitizer (HIPAD, Houston Instruments, Houston, Tex.). The calculations were performed by integrating 50 sections per cycle of the synchronized blood flow velocity and aortic diameter traces. The aortic stroke volume was calculated by the equation[6]:

$$Q = \frac{\int_t V \cdot d^2 \cdot \pi}{4 \cdot \cos 45°}$$

where t = pulse duration, Q = stroke volume, V = mean blood flow velocity, and d = vessel diameter.

The aortic stroke volume was also correlated to the fetal weight estimated from the ultrasonographically measured fetal head and abdominal diameters.[10] From the values of the volume blood flow (Q′) in ml/min (Q′ = Q · FHR) (where FHR = fetal heart rate) and the mean blood flow velocity (V), an effective diameter (Deff) was obtained according to the equation[6]:

$$\text{Deff} = \sqrt{\frac{4 \cdot Q'}{V \cdot \pi \cdot 60}}$$

Deff was then compared with the mean aortic diameter measured with the echo tracker. To be able to study the time intervals between the velocity and the diameter curves, the velocity signals were corrected for the delay of 20 milliseconds caused by the mean velocity estimator.

Statistics were on the basis of the Student *t* test for paired observations and the Mann-Whitney rank sum test for unpaired observations.

Twelve healthy women with uncomplicated singleton pregnancies participated in the study after they gave their informed consent. Three longitudinal measurements were performed on the descending aorta of each fetus (at gestational ages 28 to 29, 33 to 34, and 38 to 39 completed weeks). Gestational age had been ascertained in all fetuses by ultrasonographic fetometry in early pregnancy.

The ultrasonographic measurements of the blood flow velocity and the diameter were obtained in each fetus just above the level of the fetal diaphragm and that of the aortic bifurcation. Some measurements were not applicable either because of difficulty in identification of the recorded fetal QRS complexes or because of nonconcurrent cycles in the blood flow velocity and the diameter curves.

Results

Table I shows the mean values (±SD) of FHR, mean blood flow velocity, aortic stroke volume, weight-related aortic stroke volume, the effective diameter, and the mean diameter on the basis of the number of accepted recordings at the thoracic and abdominal levels of the descending aorta in the three gestational periods.

Neither the FHR nor the mean blood flow velocity changed significantly with gestational age. The aortic stroke volume, when correlated to estimated fetal weight, varied slightly in the thoracic aorta but showed a tendency in the abdominal aorta to decrease with advancing gestational age.

The mean and the effective diameter both increased linearly with gestational age. The effective diameter was significantly greater (p in the range 0.0001 to 0.0016) than the mean diameter at both levels of the aorta in all three gestational periods. The relative difference, expressed in percentage of the mean diameter, showed a decreasing tendency with advancing gestational age at both levels of the aorta. The relative difference was more pronounced in the thoracic than in the abdominal part of the vessel.

Table II shows the mean values (±SD) for the time interval between the first peak of the QRS complex and the onset of the velocity and of the diameter curves, respectively, and for the time interval between the first peak of the QRS complex and the maximum of the velocity and of the diameter curves, respectively.

The onset of the systolic increase in velocity slightly preceded that of the diameter, except in late pregnancy, at the thoracic level of the aorta. The systolic velocity peak significantly preceded (p in the range 0.0001 to 0.0014) the systolic diameter peak. The relative time difference, expressed in percentage of the time interval between the first peak of the QRS complex and the velocity peak, was more pronounced in the thoracic than in the abdominal part of the fetal aorta, irrespective of gestational age. A slightly smaller relative difference at both levels of the vessel was also seen near term.

Neither the diameter difference (Deff − Dmean)

nor the time lag between velocity and diameter peak was significantly correlated to FHR.

Comment

Noninvasive measurements with the use of combined Doppler and real-time ultrasonographic techniques,[1, 11] are extensively used for fetal blood flow studies in obstetrics. The estimation of peripheral resistance in the fetal and placental circulation on the basis of various waveform parameters and indices calculated from registrations of blood flow velocity[12-14] has been of particular interest. When calculating volume blood flow from blood flow velocity and vessel diameter one has to be aware of certain technical drawbacks. For instance, simultaneous measurement of blood flow velocity and vessel diameter with independent ultrasonographic equipment is impossible because of ultrasonographic interference. A method for the synchronization of blood flow velocity and diameter curves with fetal ECG signals has been applied for the study of the time difference between the velocity and the diameter traces and for the study of the accuracy of volume blood flow estimation at the thoracic and abdominal levels of the fetal aorta during the course of the third trimester.

In the present study the values of mean blood flow velocity and weight-related aortic stroke volume corresponded fairly well to earlier findings.[6, 15] The quite small time lags between the curves for onset of velocity and diameter, consistent with data from Lingman et al.[6] at both levels and in all three gestational periods, are probably insignificant in view of the time resolution limit of the digitizer used for the analysis. Thus the onset of the systolic blood flow velocity increase and the vessel expansion can probably be regarded as simultaneous. Lingman et al.[6] showed both a significant time difference between the systolic velocity peak and the diameter peak and an accompanying larger effective diameter, compared with the means of systolic and diastolic diameter, at the thoracic level of the aorta in term fetuses. In our study the mean blood flow velocity peak occurred significantly earlier than the diameter peak at both the thoracic and the abdominal level in all three gestational periods investigated, the difference being more pronounced than that previously reported.[6]

The main source of error in the calculation of volume blood flow is probably the measurement of the vessel diameter.[2] The time lag between the velocity and the diameter courses is usually not taken into account. The differences between the effective and the mean aortic diameter in the present study caused an underestimation of the volume blood flow both in the thoracic and in the abdominal aorta. The relative significance of the difference seems to be slightly greater in earlier pregnancy and in the thoracic aorta than in term pregnancy and in the abdominal part of the vessel, the volume error values being 7.9%, 5.9%, and 5.3% in the

thoracic aorta and 5.9%, 5.5%, and 3.9% in the abdominal aorta in the respective gestational period. The blood flow error reported by Lingman et al.[6] for the term fetuses was 6%.

The tendency toward a less pronounced relative time difference between the peak of the velocity curve and of the diameter curve in the abdominal aorta, vis-a-vis the thoracic part of the fetal aorta, in our study can probably be attributed to a decreasing crest time (time from the onset to the peak of the diameter curve) with increasing distance from the heart, as earlier described in the fetus by Sindberg Eriksen et al.[16] No obvious time-lag differences, conceivably resulting from changes in viscoelastic properties in the fetal aorta with increasing gestational age, were seen.

The study has confirmed earlier results[6] and has given preliminary information on longitudinal trends in the course of pregnancy. The error caused by the nonsimultaneous measurements of blood flow velocity and diameter and by use of the mean diameter instead of the effective diameter in calculation of volume blood flow was found to be <8% and thus probably of little practical importance.

Blood pressure measured telemetrically from home throughout pregnancy

Paul Mooney, MRCOG, Kevin J. Dalton, PhD, MRCOG, Helen E. Swindells, RGN, RM, Sally Rushant, RGN, RM, Wendy Cartwright, BA, and David Juett, BSc
Cambridge, England

Sixty-eight healthy pregnant women measured their blood pressure at home for 1 day every 4 weeks from 14 weeks' gestation until delivery. Blood pressure measurements were made with the Cambridge blood pressure telemetry system, which was composed of a Dinamap 1846 monitor linked to and controlled by a dedicated microprocessor which communicated transtelephonically with a hospital-based microcomputer. On each measurement day each woman measured her blood pressure five times: on first rising and then at 10 AM, 2 PM, 6 PM and 10 PM. At each measurement session the blood pressure was automatically taken 10 times at 1-minute intervals. A total of 23,790 individual blood pressure measurements were analyzed. Systolic, diastolic, and mean arterial blood pressures were lowest at 18 weeks' gestation, rising slowly thereafter at a rate of 0.4 mm Hg systolic and 0.2 mm Hg diastolic per week. The maternal pulse rate also increased steadily after 18 weeks at a rate of 0.25 beats/min per week. There was a strong correlation between the blood pressures at 18, 26, and 38 weeks. All blood pressure parameters were significantly lower on first rising than at other times of the day, although the differences were small: 5 mm Hg for systolic, 4 mm Hg for mean arterial, and 3 mm Hg for diastolic blood pressure. After 10 AM, however, there was no significant daytime variation in any blood pressure parameter, indicating that for most purposes the time of day at which pressure measurements are made is unimportant. (AM J OBSTET GYNECOL 1990;163:30-6.)

Key words: Pregnancy, blood pressure, telemetry, computer, Dinamap, home care

Ever since the association between eclampsia and hypertension was first recognized, the measurement of blood pressure throughout pregnancy has become an essential part of good antenatal care. However, before an abnormality in blood pressure can be recognized, a normal range must first be defined.

The principal aim of this study was to determine the range of blood pressure throughout pregnancy. A secondary aim was to determine whether there is any significant variation in blood pressure at different times of the day. For the purpose of this study we used a computerized system for the telemetry of maternal blood pressure from home.

Although there are many published studies in this field,[1-7] all are based on data collected in the hospital or the obstetrician's office. No previous study has measured the blood pressure throughout pregnancy in the woman's normal environment, her own home. Furthermore, no previous study has included measurements made at different times of the day throughout pregnancy.

Patients, equipment, and methods

Patients. We recruited 68 women who lived within a 30-mile radius of the Rosie Maternity Hospital in Cambridge, and who first attended the antenatal clinic before 14 weeks' gestation as determined by the date of their last menstrual period. Patients were recruited sequentially (in the order in which they attended the booking clinic). No attempt was made to select normal pregnancies for inclusion in the study, or to exclude women with hypertension or other medical problems.

Equipment. The home telemetry equipment consisted of a Dinamap 1846SX blood pressure monitor (Critikon, Sunninghill, Berks, U.K.) that was linked to, and controlled by, a microprocessor built to our own specification. The Dinamap monitor uses an oscillometric technique to measure systolic, diastolic, mean arterial blood pressures, and pulse and is of proved accuracy[8] and reliability.[9]

The microprocessor unit contained a single-board microcomputer, an autodialling telephonic modem (able to dial preprogrammed numbers automatically), and an interface through which the monitor was controlled. At each measurement session the micropro-

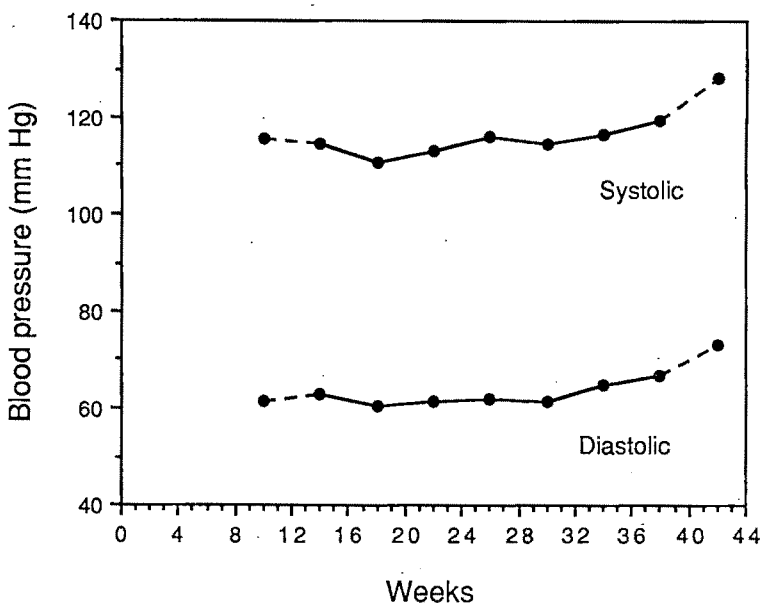

Fig. 1. The changes in systolic and diastolic blood pressures which occurred with gestation, average of all patients. The *dotted* parts of the line indicate regions where the data represent only five patients.

cessor instructed the instrument to make 10 blood pressure determinations at 1-minute intervals, and then memorized the results. When the 10 readings were complete, the microprocessor automatically transmitted the results from the patient's home over the public telephone network to a hospital-based Amstrad (IBM PC-XT compatible) microcomputer (Amstrad, Brentwood, Essex, U.K.). Our blood pressure telemetry system has been substantially improved since it was first described.[10]

Methods. Each woman was taught to use the system herself and was then able to conduct her own automated 10-minute measurement session at home without supervision. During each session the patient sat quietly with the cuff on her right arm, which rested in her lap. In this position the cuff was approximately at the level of the heart. All women measured their blood pressures at home in this way for one complete day every 4 weeks from 14 weeks until delivery. Measurements were made on rising, and then at 10 AM, 2 PM, 6 PM, and 10 PM. Women were encouraged to rest for 5 minutes before each measurement session.

To avoid any possibility that the results of home blood pressure measurements could influence clinical management, the results of home blood pressure readings were not shown to patients' own obstetricians.

All gestational ages were calculated from an ultrasonographic measurement of biparietal diameter at approximately 18 weeks. To determine any trend with gestational age, blood pressure and pulse data were averaged over 4-week epochs. Data were analyzed with the SPSS/PC program.

Results

There were 26 nulliparous and 42 parous women with an average age of 26.7 years (range, 19 to 39 years). All were white with singleton pregnancies and none were receiving any medication (other than iron or vitamins). The ages of the parous and nulliparous women were not significantly different. A total of 2379 measurement sessions were made. Each session consisted of 10 measurements; thus 23,790 individual measurements of blood pressure and pulse were made.

Blood pressure measurements began at 14 weeks' after the last menstrual period, before gestational ages had been established ultrasonographically. In five pregnancies the ultrasonographically determined gestational ages were substantially less than had been suggested by the duration of amenorrhea, and for this reason the data from these women begin at 10 weeks' gestation.

Ten women did not complete their 38-week blood pressure measurements; six went into spontaneous labor, three underwent elective cesarean section, and labor was induced in one. Fifty-three women were delivered between 38 and 42 weeks; 31 went into spontaneous labor, six had elective cesarean sections, and in five labor was induced. Two women were admitted to the hospital at 38 and 39 weeks' gestation because hypertension (150/90 and 160/100 mm Hg, respectively)

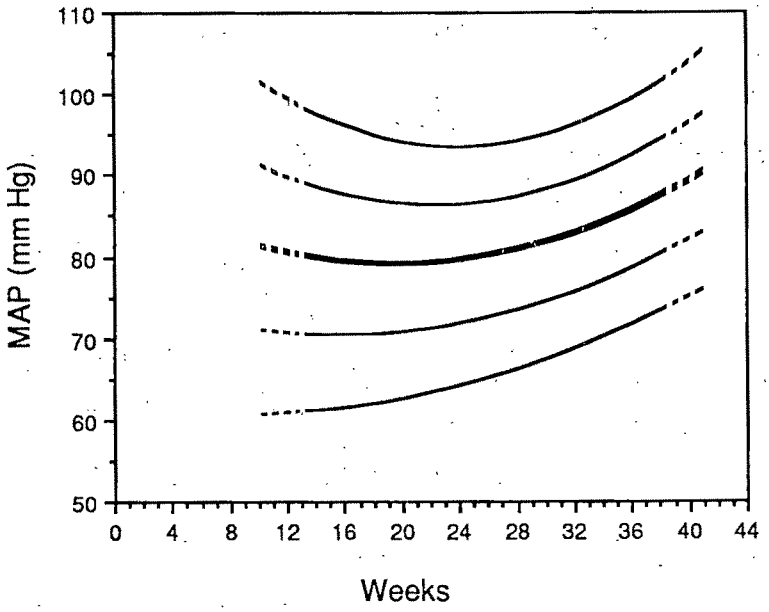

Fig. 2. Smoothed curves show the changes in mean arterial pressure that occurred with gestation, averages of all patients. The *thick line* is the 50th percentile, the *thinner lines* above and below represent ±1 and 2 SDs. The *dotted* parts of the line indicate regions in which the data represent only five patients.

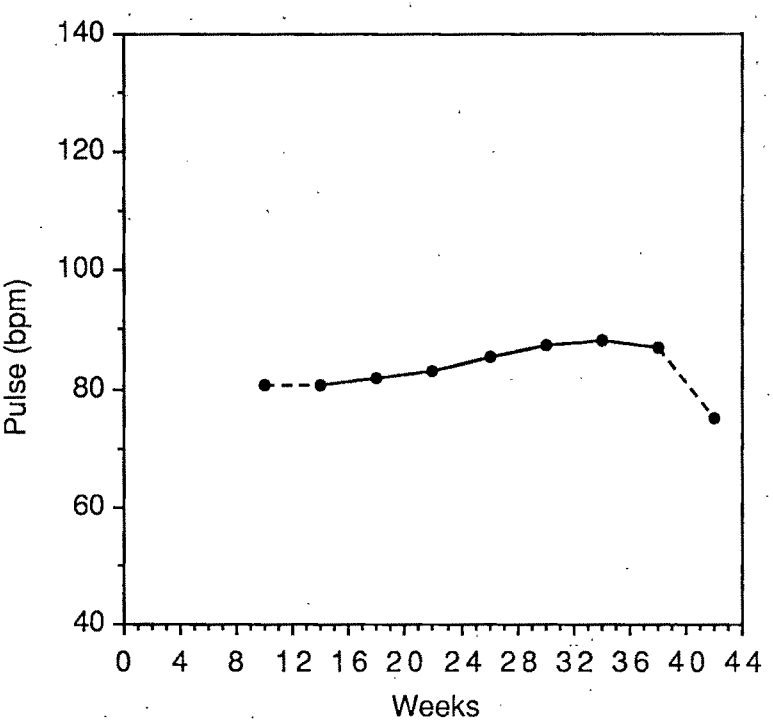

Fig. 3. The changes in pulse rate which occurred with gestation (averages of all patients). The *dotted* parts of the line indicate regions where the data represent only five patients.

was detected with a conventional mercury sphygmomanometer in the antenatal clinic, and labor was subsequently induced.

Only five women completed blood pressure sessions at 42 weeks' gestation. Because of the small numbers of patients providing 10-week and 42-week blood pressure results (five in each case), the data from these gestational ages should be interpreted with caution.

Blood pressure and pulse changes with maternal

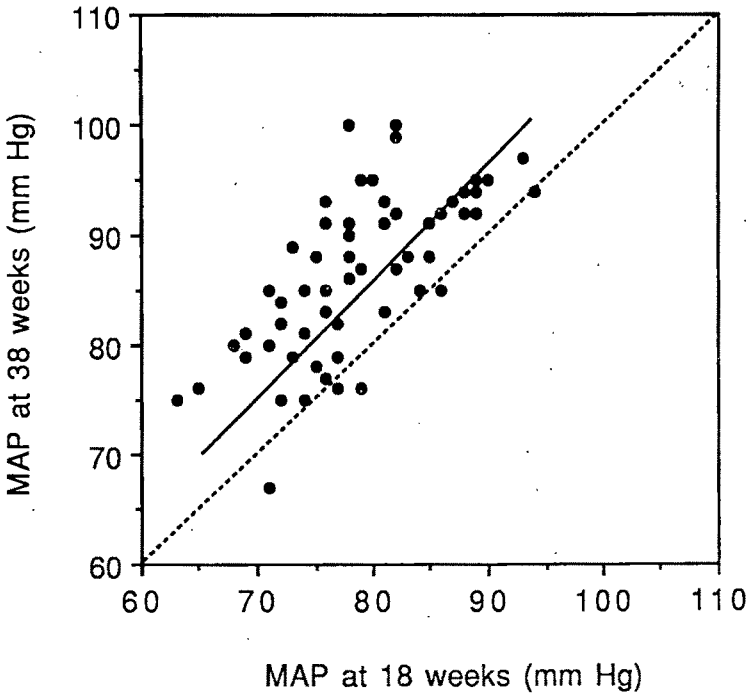

Fig. 4. Mean arterial pressure at 38 weeks' gestation plotted against mean arterial pressure at 18 weeks for all patients. *Dashed line,* Line of equality; *solid line,* correlation line.

age and parity. We found no correlation between maternal age and any blood pressure parameter or pulse rate. There were no significant differences in blood pressure or pulse rate between parous and nulliparous women at any gestational age, and therefore we combined the data from both groups.

Blood pressure and pulse changes with gestational age. Fig. 1 shows the systolic and diastolic blood pressures averaged over 4-week epochs throughout pregnancy. The lowest readings were obtained at 18 weeks' gestation: 111 mm Hg systolic and 61 mm Hg diastolic on average. Pressures slowly increased thereafter, and by 38 weeks'gestation they had reached averages of 119 mm Hg systolic and 65 mm Hg diastolic, average increases of 0.4 and 0.2 mm Hg per week, respectively. Fig. 2 shows the trend in mean arterial pressure throughout pregnancy, averaged over all patients, together with smoothed curves representing 1 and 2 SDs above and below the mean.

Fig. 3 shows the average pulse rate in 4-week epochs throughout pregnancy. The pulse increases from 82 beats/min at 18 weeks to 87 beats/min at 38 weeks, an increase of 0.25 beats/min per week.

We found strong correlations between the mean arterial pressure at 18 and 38 weeks ($r = 0.60$, $p < 0.0001$) and the mean arterial pressure at 26 and 38 weeks ($r = 0.69$, $p < 0.0001$) as illustrated in Figs. 4 and 5, respectively. In both figures the correlation line and the line of equality are shown to demonstrate the blood pressure shift that occurs from the earlier to the later gestation in each case. We found similar relationships with systolic and diastolic pressures (data not shown, $p < 0.0001$ in all cases).

Blood pressure and pulse changes with time of day. Fig. 6 shows the changes in blood pressure that occurred during the day. As can be seen, the systolic, diastolic, and mean arterial pressures were significantly lower on first rising than from 10 AM and afterward ($t = -6.3, -3.3, -3.9$ and $p < 0.001, 0.01, 0.001$), although the differences were small: 5, 3, and 4 mm Hg, respectively. After 10 AM there was no significant change in any measure of blood pressure.

Fig. 7 shows that the pulse rate was significantly higher from 10 AM to 2 PM than before ($t = 8.5$, $p < 0.001$) or after ($t = 10.8$, $p < 0.001$) these times. Again, the actual difference was small: 4 beats/min.

Comment

This is the first study of blood pressure in normal pregnancy to be based on objective measurements made exclusively in the subjects' own homes, where they are free of the distractions and anxieties that might influence clinic or office measurements.

An automatic machine such as the Dinamap monitor is ideal in epidemiologic studies because it eliminates observer bias, digit preference, and intraobserver and interobserver variation[11] that have weakened studies with the conventional (true zero) mercury sphygmo-

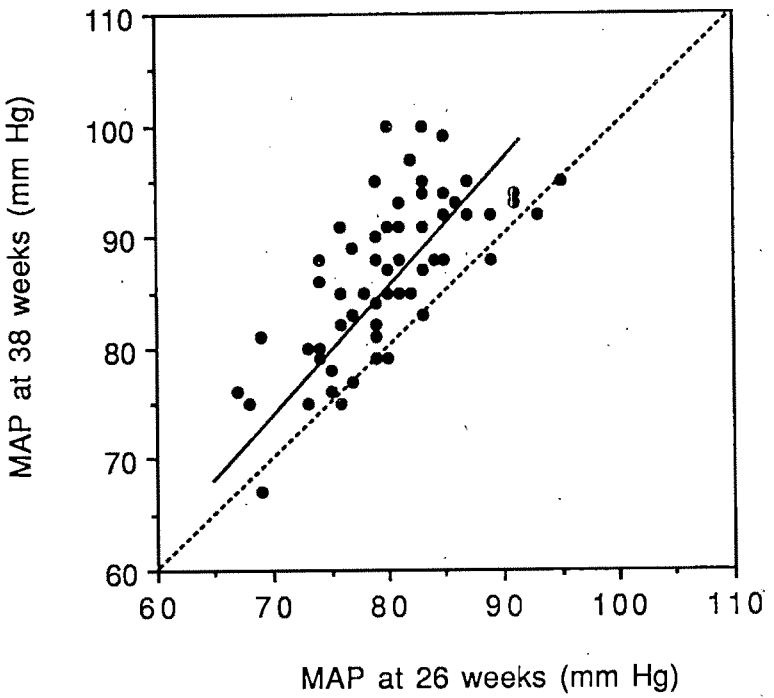

Fig. 5. Mean arterial pressure at 38 weeks' gestation plotted against mean arterial pressure at 26 weeks for all patients. *Dashed line,* Line of equality; *solid line,* correlation line.

manometer,[4, 5, 7] and it is capable of remote control by a microprocessor system. The American Heart Association has recommended that phase V of the Korotkoff sounds be used to determine the diastolic end point when auscultatory methods are used to determine blood pressure.[12] This advice is often difficult to follow in pregnancy because phase V is commonly absent[3] hence obstetricians generally use phase IV instead. De-

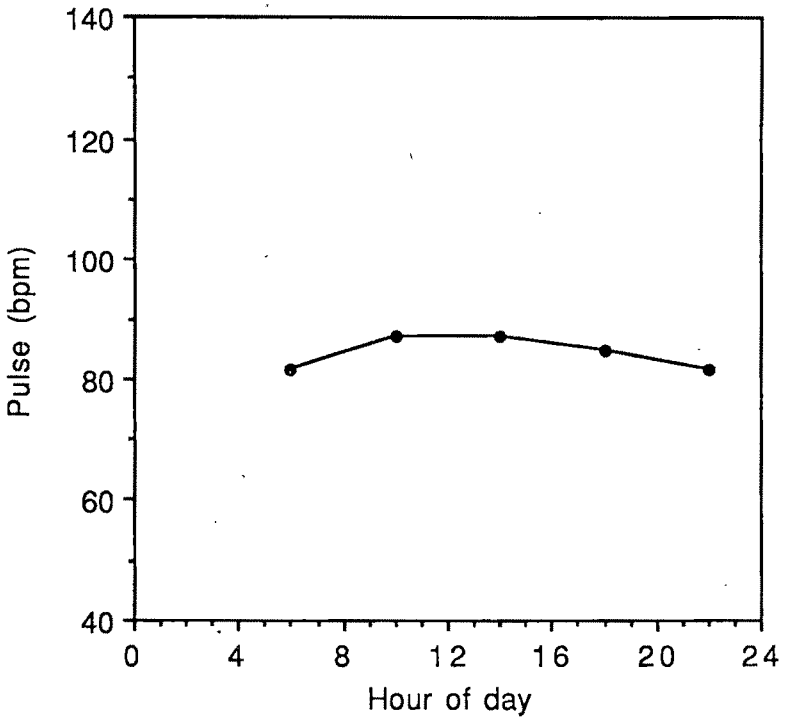

Fig. 7. The changes in pulse rate which occurred during the day (averages of all patients).

vices such as the Dinamap that use an oscillometric technique to determine the blood pressure do not rely on the Korotkoff sounds, and should give equally accurate results in pregnant and nonpregnant subjects.

When blood pressure trends are determined throughout pregnancy, some authors[2, 6, 7] have deliberately excluded from their studies patients whose hypertension developed eventually. However, because most pregnant women in whom a blood pressure >140/90 mm Hg develops may simply represent the upper extreme of a normal distribution, rather than have genuine preeclampsia, their exclusion from analysis will give a misleading picture of the blood pressure of the pregnant population in general. We have therefore included data from all our patients, regardless of whether they met the clinical diagnostic criteria for "preeclampsia." However, even if we had excluded blood pressure data from those patients with hypertension, we would have only slightly reduced our average pressures through pregnancy because only two of our patients came into this category, and they both provided data from 14 to 38 weeks' gestation.

The blood pressure readings we obtained were lower than those reported by Henry,[1] Andros and Arbour,[2] Page and Christianson,[3] and Wilson et al.[5] who used conventional sphygmomanometers, and Moutquin et al.[6] who used a Dinamap monitor, and higher than those reported by McGillivray et al.,[3] who used the London School of Hygiene sphygmomanometer. The lack of significant daytime variation in the blood pressure after 10 AM is consistent with previous findings in both nonpregnant[13] and pregnant subjects[14, 15] and confirms that, for most purposes, the time of day at which pressure measurements are made is unimportant. Our finding that the blood pressures of parous and nulliparous women are not significantly different is in agreement with the findings of Henry[1] and Moutquin et al.[6]

Large swings of blood pressure may occur over relatively short periods. Dalton et al.[10] found a modal swing of 23 mm Hg in the systolic and 13 mm Hg in the diastolic blood pressure, and a maximum swing of 41 mm Hg in the systolic blood pressure within a period of only 10 minutes in 90 measurement sessions from the homes of pregnant women. Mooney and Dalton[16] measured the blood pressures of a group of 51 hypertensive pregnant women every 5 minutes for 1 hour. They found a mean swing of 24 mm Hg in the systolic and 19 mm Hg in the diastolic blood pressure, and a maximum swing of 50 mm Hg in the systolic and 31 mm Hg in the diastolic blood pressure. A consequence of these findings is that large sampling errors may occur if reliance is placed on single blood pressure measurements. A 10-measurement series, as in our study, minimizes the effect of such errors. The only other study of blood pressure in pregnancy to have addressed the problem of sampling errors is that of Moutquin et al.[6] They used a Dinamap 845 monitor to measure each

woman's blood pressure repeatedly at 2-minute intervals until a discrepancy of less than 5 mm Hg was observed. Their technique, although preferable to single measurements alone, remains prone to sampling errors.

Our results provided good correlations between pressures at 14, 26, and 38 weeks' gestation. A 10-minute Dinamap pressure screen at approximately 18 weeks' gestation may be more useful in predicting patients in whom hypertension will develop during late pregnancy than were earlier screening tests based on "one-off" pressure measurements made in the office.[17] However, a large prospective trial is necessary to evaluate the predictive usefulness of such 10-minute pressure screening, whether performed in the obstetrician's office or in the patient's home.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1990 issues from the Publisher, at a cost of $56.00 ($79.00 international) for Vol. 162 (January-June) and Vol. 163 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318, USA; phone (800) 325-4177, ext. 7351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

β-Adrenergic receptor blockade in the management of pregnant women with mitral stenosis

Saad M. Al Kasab, FRCP, Taher Sabag, MD, Muayed Al Zaibag, FRCP, Mohamed Awaad, MRCOG, Issam Al Bitar, MD, Murtada A. Halim, MRCP, Moheeb A. Abdullah, MRCP, Maie Shahed, MRCP, Vijayaraghavan Rajendran, MRCP, William Sawyer, MB, ChB

Riyadh, Saudi Arabia

Twenty-five pregnant women with symptomatic mitral valve stenosis (mean valve area, 1.1 ± 0.25 cm^2) were managed by initiation or modification of β-adrenergic receptor blockade with the use of either propranolol or atenolol. Significant improvement of symptoms occurred in 23 patients (92%) ($p < 0.01$); the mean maternal heart rate was reduced significantly from 86 ± 4 to 78 ± 5 beats/min ($p < 0.0001$). The overall fetal heart rate ranged between 130 to 150 beats/min during treatment. Only two patients required urgent closed mitral valvotomy, after pulmonary edema developed as a result of poor compliance to β-blockade. All patients were safely delivered of infants at term. Fetal heart rates ranged between 120 to 140 beats/min at delivery. There was no maternal or fetal death. Pregnant woman with symptomatic mitral valve stenosis can be safely managed with β-blockade, giving significant reduction in the incidence of pulmonary edema with no unwanted neonatal side effect. (Am J Obstet Gynecol 1990;163:37-40.)

Key words: Mitral stenosis, pregnancy, β-adrenergic receptor

Mitral stenosis continues to be the most common rheumatic valvular lesion encountered in pregnancy, particularly in developing countries. Cardiac surgery during pregnancy presents a risk to both fetus and mother, and should be performed only when absolutely necessary.[1,2]

This study shows that symptomatic pregnant women with moderate to severe mitral stenosis can be managed conservatively by β-adrenergic receptor blockade without the need of exposure to the risk of closed mitral valvotomy.

Patients and method

Between June 1985 and June 1988, 25 pregnant woman with moderate to severe mitral stenosis (mitral valve area range, 0.6 to 1.5 cm^2; mean, 1.1 ± 0.25 cm^2) were delivered of infants in the Armed Forces Hospital, Riyadh, Saudi Arabia. Their ages ranged from 15 to 40 years (mean, 28 years).

Before pregnancy 72% of the patients were symptomatic: seven were in New York Heart Association (NYHA) class I, 14 in class II, and four in class III. In all 25 patients, symptoms either developed or became more severe during pregnancy; three patients were in NYHA class I but had palpitations, 12 were in class II, seven in class III, and three in class IV (Fig. 1). Before pregnancy one third of patients had palpitations in addition to shortness of breath; the palpitations became worse during pregnancy. Palpitations developed in an additional one third during the pregnancy.

During pregnancy all patients were in sinus rhythm and had clinical evidence of moderate to severe mitral stenosis; eight patients also had mild aortic regurgitation, seven had mild mitral regurgitation, and four had mild tricuspid regurgitation. In all patients the nature of the underlying cardiac lesion was already documented, either by two-dimensional echocardiogram and Doppler ultrasonographic studies before and during pregnancy or by cardiac catheterization before pregnancy.

All patients were followed-up in a combined antenatal and cardiac clinic at 4-week intervals in the first and second trimester and at every 2 weeks in the last trimester. At each visit the patient had a complete physical examination. Maternal heart rate and blood pressure, fetal position and presentation, and fetal heart rate were recorded throughout pregnancy; the mean values for each patient are shown in Table I.

Before pregnancy two thirds of the patients were receiving digoxin 0.25 mg once daily in addition to a diuretic, either hydrochlorothiazide 25 mg daily or frusemide 40 mg daily. β-Blockade was given as new therapy during the pregnancy in 16 patients; 14 of these

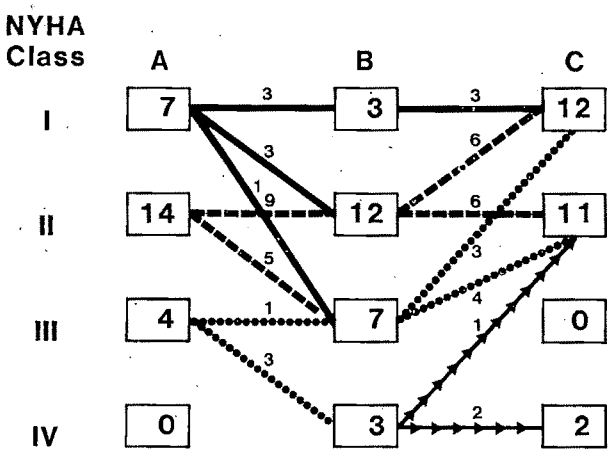

Fig. 1. New York Heart Association class *(NYHA)* changes in symptomatology: **A,** before pregnancy; **B,** during pregnancy before initiation or increase of β-blockade therapy; **C,** during pregnancy after adequate β-blockade. Note significant improvement from **B** to **C** ($p < 0.01$).

constitute group I (pulmonary edema developed in two patients, requiring closed valvotomy). In nine patients already receiving either propranolol or atenolol, β-blockade dosage was increased (group II). Overall, atenolol 100 to 200 mg daily was administered to 11 patients and propanolol 10 to 80 mg was administered three times daily to 14 patients.

Patients were routinely admitted to the hospital 3 to 7 days before the expected date of delivery, except for one patient with severe mitral stenosis (mitral valve area, 0.9 cm^2), who was admitted for the entire third trimester.

Statistics. Data are expressed as a mean ± SD. The paired Student t test and χ^2 square test were used to test the difference between means.

Results

During pregnancy before initiation or increase of β-blockade therapy, 15 patients were in either NYHA class I or II and 10 were in either class III or IV. After initiation or modification of previous β-blockade, 23 patients (92%) improved significantly to either class I or II ($p < 0.01$) (Fig. 1). Two patients (8%) with severe mitral stenosis (mitral valve areas, 0.6 and 1 cm^2, respectively, assessed by continuous-wave Doppler ultrasonography) had poor complicance to β-blockade, with heart rates not reduced below 90 beats/min. Pulmonary edema developed in both patients. Hypotension developed in the first patient after a small dose of propranolol, without control of her heart rate; she had a closed mitral valvotomy in the second trimester. The second patient was admitted in pulmonary edema twice; during the second admission in the second trimester she underwent closed mitral valvotomy. Both pregnancies continued to a safe vaginal delivery. In the remaining 23 patients the overall mean maternal heart rate was reduced significantly from 86 ± 4 to 78 ± 5 beats/min. In group I the reduction was from 88 ± 3 to 78 ± 5 beats/min ($p < 0.001$) after initiation of β-blockade therapy; in group II, after increased β-blockade therapy, the mean maternal heart rate was reduced from 84 ± 3 to 77 ± 5 beats/min ($p < 0.005$). Overall, the fetal heart rate ranged between 130 to 154 beats/min during β-blockade treatment (Table I).

All 25 patients had a vertex presentation and were safely delivered after 37 to 39 weeks' gestation. Twenty were delivered vaginally and five were by cesarian section—one because of placenta previa, three because of previous cesarian section, and one because of severe mitral stenosis with pulmonary hypertension in whom it was thought unsafe to attempt vaginal delivery.

For the majority of those patients vaginally delivered of infants the second stage of delivery was short, probably because of the small-sized fetus, but two patients required forceps extraction because of second-stage delay. In two other patients 40 mg of intravenous Lasix furosemide preparation was used intrapartum to achieve preload reduction.

The mean weight of the babies was 2.8 ± 0.4 kg (range, 2.1 to 3.5 kg) with a mean Apgar score of 9 (range, 8 to 10) (Table I). The mean heart rate ranged between 120 to 140 beats/min. There was no maternal or fetal death or fetal morbidity in this series. Three patients had mitral balloon valvotomy and one had open mitral valvotomy 2 months after delivery.

Comment

This study shows that β-blockade can be used successfully in the management of pregnant women with moderate to severe, symptomatic, rheumatic mitral stenosis. All were safely delivered of a live infant at term.

The specific hemodynamic changes that occurred during pregnancy are a 40% increase in the cardiac output, a 10% to 20% increase in heart rate, a 30% to 40% increase in the blood volume, and increased irritability of the left atrium. The latter may precipitate fast atrial fibrillation, particularly in patients with mitral stenosis.[3] The primary hemodynamic effect of severe mitral stenosis is obstruction of blood flow from the left atrium to left ventricle during diastole. Tachycardia, or fast atrial fibrillation, will increase both the left atrial and subsequently pulmonary vascular pressures, leading to pulmonary edema. In this study the main objective was to control the maternal heart rate, maintaining a rate of 70 to 86 beats/min, particularly during any effort. This was achieved with β-blockade except in two patients with poor compliance to the therapy

Table I. Clinical characteristics of mother and fetus during pregnancy

Patient	Age (yr)	Mean maternal heart rate (beats/min)		Mean systemic blood pressure (mm Hg)	Mitral valve area (cm^2)	Mean fetal heart rate	Baby weight	Type of delivery
		Before β-blockade	After β-blockade

Mean maternal heart rate ± SD = 86 ± 4 before and 78 ± 5 after adequate beta blockade, excluding patients 8 and 12.
*Group II (9 patients) who already were receiving β-blockade before pregnancy, and the dosage subsequently modified.
†Patients 8 and 12 underwent closed mitral valvotomy.

whose heart rates were >100 beats/min before treatment and were not lowered to <90 beats/min after treatment. Control of the heart rate prevents the increase in pulmonary wedge pressure with a consequent increase in mitral valve gradient, which may precipitate pulmonary edema.

Szekely[4] reported an overall mortality of 1% in all patients with mitral stenosis in pregnancy, regardless of NYHA classification; in severe cases (NYHA class III or IV) maternal mortality rises to 4 to 5%. In the presence of atrial fibrillation, mortality further increases significantly to 17%.[5] In our series there were no deaths, despite the fact that two thirds of the patients had severe mitral stenosis (mitral valve area, <1.1 cm^2).

Closed mitral valvotomy in pregnancy is not without maternal or fetal morbidity or mortality. In 29 patients who underwent closed mitral valvotomy during pregnancy, one maternal and two neonatal deaths were reported.[6] Vosloo[7] and Zitnik[8] reported fetal mortality of 12.2% and 33%, respectively, after mitral valvotomy during pregnancy. On the other hand, closed mitral valvotomy may be lifesaving in cases of medically uncontrolled pulmonary edema during pregnancy. Only two of the patients in this report underwent closed mitral valvotomy during pregnancy because of pulmonary edema as a result of poor compliance to medication, with no fetal or maternal death.

This study shows that β-blockade decreases the risk of development of pulmonary edema, which is the most important cause of maternal mortality[9, 10] during pregnancy. Previously published reports concerning the use of propranolol during pregnancy seem contradictory. Koliobash[11] and Turner[12] used propranolol in hypertrophic cardiomyopathy during labor; they reported no side effects on the neonates who were recorded as healthy at birth. However, Reed[13] and Goldstone[14] reported individual cases in which the mother received high doses of propranolol during pregnancy and labor for the treatment of hypertension and ventricular tachycardia. The infants had a low Apgar score and hypoglycemia developed, but their subsequent courses were uneventful. The present study revealed no side effects on either the Apgar score or heart rates of the neonates. The weights of most of the newborns in our series were relatively low; this is most likely because of the chronic low cardiac output as a result of mitral stenosis.

In conclusion, we believe that significant mitral stenosis in pregnancy can be safely managed with β-blockade with no unwanted effect on the mother or

neonate. Furthermore β-blockade was shown to reduce the incidence of development of pulmonary edema during pregnancy.

Addendum

Since the completion of this article an additional 20 pregnant women with moderate to severe mitral stenosis have been successfully treated to the completion of gestation with β-adrenergic receptor blockade; none required closed mitral valvotomy.

Cocaine-related maternal death

Gene Burkett, MD,[a] Emmalee S. Bandstra, MD,[b] Jay Cohen, MD,[a] Bernard Steele, MD,[c] and Diana Palow, RN[a]

Miami, Florida

Hemodynamic overload, cardiac ischemia, and arrhythmia are postulated to originate from "sex-cocaine" syndrome resulting in maternal and fetal death. High concentrations of cocaine and metabolites in maternal blood, urine, and nasal secretions confirmed recent ingestion. Changes in the maternal life-style may have contributed to the poor pregnancy outcome. (Am J Obstet Gynecol 1990;163:40-1.)

Key words: Sex-cocaine syndrome, maternal death

Rapid proliferation of cocaine use among women of reproductive age is partially due to unlimited availability of cheaper alkaloid cocaine ("crack"). This produces a life-style particularly inimical to pregnancy.

Cerebrovascular accidents, cardiac arrhythmias, and infarction have resulted in serious illnesses or death in young abusers.[1] High perinatal morbidity and mortality rates are linked to cocaine.[2] Affected neonates demonstrate lifelong neurodevelopmental deficits, recurrent febrile illnesses, and sudden infant death syndrome.

We report a case of both maternal and fetal death related to cocaine in a bizarre cluster of events that unfortunately is likely to recur.

Case report

A 26-year-old black woman, gravida 4, para 3-0-0-3, was brought to the emergency room at University of Miami/Jackson Memorial Hospital Center (UM/JMHC) by Fire Rescue personnel on April 5, 1988. At 2:13 AM they found her unconscious without pulse, respirations, or blood pressure. Electrocardiogram showed severe bradycardia. She was 7 to 8 months

From the Department of Obstetrics and Gynecology,[a] the Department of Neonatology,[b] and the Department of Pathology,[c] University of Miami School of Medicine.

pregnant and the fetal heart was beating. Intubation, oxygen administration, and mechanical external cardiac massage were immediately established.

On arrival to the hospital at 2:55 AM she was unconscious and cyanotic with no detectable pulse or blood pressure and unresponsive pupils. Electrocardiogram showed asystole. Intravenous ephedrine, bicarbonate, and atropine, external cardiac massage, and mechanical ventilation produced no effect. Simultaneously, obstetric evaluation showed a fetus of 32 weeks' gestation, a tense uterus, and a fetal heart rate of 40 beats/min. There was no blood or amniotic fluid from a long closed cervix. Agonal cesarean section was done, and a female infant was delivered at 2:57 AM, 2 minutes after arrival. There was 30% abruptio placentae. Apgar scores were 1 and 0 (at 1 and 5 minutes, respectively). Infant resuscitation was attempted unsuccessfully for 20 minutes.

Abnormal results from blood drawn on arrival were hemoglobin 10.9 gm/dl and hematocrit 35%. Red blood cell smear showed hypochromia, poikilocytosis, anisocytosis, and basophilic stipling. Base excess of −17 mEq/L, oxygen saturation of 3%, and pH of 6.82 indicated severe acidosis and hypoxemia. In blood obtained directly from the heart, the concentration of cocaine was 0.21 mg/L, benzoylecognine was 1.38 mg/L, and methylecognine was positive. Cocaine and its metabolites were detected in urine and nasal secretions.

The boyfriend said that during sexual intercourse the patient developed intense chest pain, which worsened. Gasping for air, she stumbled to the bathroom and collapsed. He vehemently denied cocaine use.

She had no prenatal care. At 26 weeks' gestation she was seen in the emergency room, complaining of a fall and a painful right hip. The uterus was soft, nontender, and approximated the dates. All vital signs were normal. Follow-up appointment to the prenatal clinic was not kept.

In three previous pregnancies, she was employed, averaged seven prenatal visits, gained 25 to 40 pounds, and was delivered of term-sized female infants. All laboratory studies were normal.

Postmortem findings for both mother and fetus were unremarkable, except for mild lung congestion in the mother. The medical examiner determined that death was caused by cocaine intoxication.

Comment

Cocaine-related maternal deaths are likely to be encountered by obstetricians, because one in every six or seven pregnant women uses cocaine. A prevalence of 12.1% detected at UM/JMHC may be an underestimate.

The medical examiner for Dade County, Florida, investigated 240 sudden, unexpected deaths, 60 of which were due to cocaine overdose while traces of the drug were noncontributory in 180.

Cocaine, an arrhythmogenic and powerful vasoconstrictor, is associated with ischemia in myocardial-cerebral infarction and intestinal gangrene in abusers. The intense anginal pain during sexual intercourse and high blood concentrations of cocaine support the postulate that our patient collapsed from acute cardiac failure that was secondary to ventricular arrhythmia and coronary ischemia. This accounts for the paucity of pathologic conditions found at autopsy.

Acute cardiac events may have been precipitated by "sex-cocaine" syndrome. Sex-induced cardiodynamic surges, higher demands of hyperdynamic circulation of pregnancy, and vasoactive stresses of high levels of cocaine presented a strain sufficient to induce malignant arrhythmia, cardiac failure, and death. Isner et al.[1] suggested that an increase in rate-pressure product may produce these events as a result of ischemia, occurring secondary to a sudden increase in myocardial demand for oxygen, triggered by sexual surges. As cocaine itself impairs oxygen-carrying capacity, further strain on this precariously balanced system will precipitate breakdown. Mother and infant were too obtunded to respond because of intense attenuation of blood flow and oxygenation to vital areas of brain and myocardium.

Contrasting the last pregnancy to previous ones illustrates life-style changes associated with cocaine users, possibly priming her for the terminal events. She was unemployed, sought no prenatal care, and showed suboptimal nutrition in blood smears. Factors inimical to pregnancy outcome besides cocaine include intermittent starvation during cocaine binging, systemic infection, sexually transmitted diseases, multiple "street" drugs, and deterioration of personal grooming, hygiene, and nutrition.[2] The severity of the problems becomes directly proportional to the amount of cocaine abuse. Maternal and fetal death represents an end point.

In animals the death rate from cocaine is twice that of heroin, and in humans unexpected cardiac[1] and neurologic disasters provide compelling evidence that cocaine is the most lethal drug yet abused. Given this, unlimited supplies, willing users, and our failure to recognize cocaine-abusing pregnant women, major catastrophies are certain occurrences.

Systemic cystic angiomatosis in pregnancy: A case presentation and review of the literature

A. Bardeguez, MD, M. Chatterjee, MD, M. Tepedino, MD, and B. Sicuranza, MD
Newark, New Jersey

Systemic cystic angiomatosis is the involvement of multiple organ systems with a congenital vascular malformation. A combination of vascular anomalies, namely lymphangioma and hemangioma, can coexist. The liver, spleen, kidney, and colon are the most commonly affected organs. The clinical presentation varies and generally reflects the involved organ system. A case of systemic cystic angiomatosis involving the spleen, liver, and kidney is presented. The diagnosis and management during pregnancy is discussed. (AM J OBSTET GYNECOL 1990;163:42-5.)

Key words: Pregnancy, systemic, cystic, angiomatosis

Lymphangiomatosis is a rare congenital malformation of the lymphatic system that generally is first seen during childhood and in young adults.[1] The term systemic cystic angiomatosis is used when the process involves multiple organ systems. The liver, spleen, kidney, and colon are the most commonly affected organs. Occasionally a combination of vascular anomalies, namely, lymphangioma and hemangioma, can coexist. Fink described the first case with spleen involvement in 1885. By 1979 fewer than 10 cases of systemic cystic angiomatosis that involved the spleen have been reported in the world literature. We present the first case of systemic cystic angiomatosis diagnosed with ultrasonography during pregnancy, a review of the literature, and our recommendation for management.

Case report

A 35-year-old white female, gravida 7, para 4, was first seen at 16 weeks' gestation with severe left upper quadrant pain of 3 months' duration associated with low-grade fever. Her medical history was significant for left nephrectomy in 1979 because of persistent hematuria. The pathologic findings were compatible with a cavernous hemangioma of the kidney.

Physical examination on admission revealed a well developed female in moderate distress with a tender, mobile left upper quadrant mass with a lower edge that was palpable 12 cm below the left costal margin; the bowel sounds were normal. There was no evidence of lymphadenopathy. Fundal height was appropriate for 16 week's gestation and fetal heart rate was normal.

6/1/19058

Initial laboratory data included the following: hematocrit 37%, platelet count 135,000, prothrombin time 9.2 (control 4.6), negative direct and indirect Coomb's test results, O positive blood type, and burr cells and decreased platelets on peripheral smear. Hemoglobin electrophoresis, hepatic and renal function studies, screening for collagen vascular disease, febrile agglutinins, carcinoembryogenic antigen, and α-fetoprotein were all within normal limits. Bone marrow findings were consistent with normal cellularity.

Abdominal ultrasonography confirmed an enlarged spleen with extensive cystic changes (Fig. 1). There was also an area of increased attenuation on the right aspect of the liver, suggestive of an intrahepatic lesion. Pelvic ultrasonographic examination confirmed a 16-week intrauterine pregnancy. The preoperative diagnosis was mild hypersplenism, probably a result of congenital cystic spleen.

The patient underwent exploratory laparotomy at 18 weeks' gestation with general anesthesia. An enlarged spleen (615 gm) measuring 17 × 12 × 7 cm was found at surgery. The irregular external surface was characterized by multiple cysts that measured 0.5 to 7 cm in diameter and contained clear or hemorrhagic fluid. The histopathologic findings were compatible with mixed lymphangioma and hemangioma structures (Figs. 2A and 2B).

The remainder of her pregnancy was uneventful. She had a normal spontaneous vaginal delivery of a male infant with Apgar scores of 9 and 10 at 1 and 5 minutes, respectively, and a birth weight of 3945 gm.

Comment

Cystic lymphangiomatosis is a benign congenital vascular malformation frequently seen in infancy and childhood. Histologically it comprises cystic spaces of varying sizes lined by endothelium and surrounded by connective tissue. Any combination of capillary, venous, arterial, and lymphatic components can occur.[1]

The pathogenesis of these lesions remains contro-

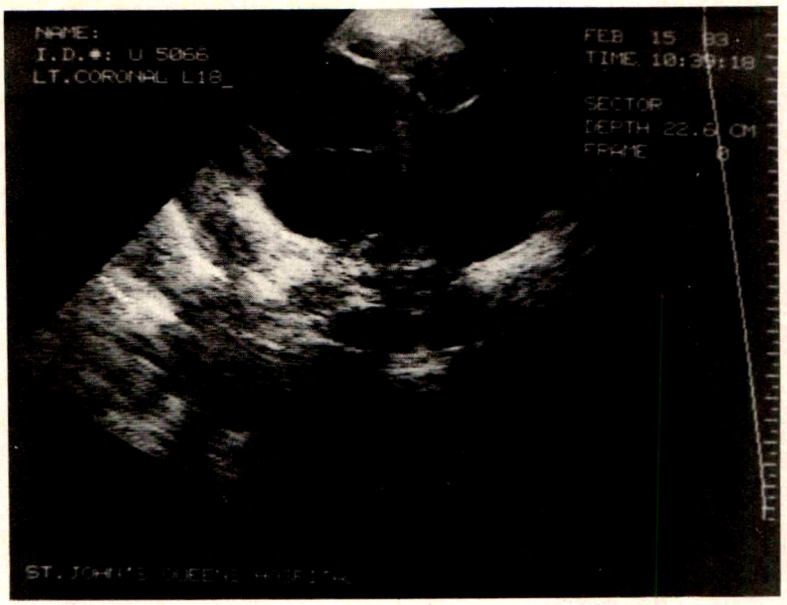

Fig. 1. Ultrasonographic view of spleen illustrates hypersplenism and extensive cystic changes.

versial. Nevertheless some authors believe that these tumors develop as areas of localized lymphatic stasis because of a congenital blockage of the regional lymphatic drainage. There is a female preponderance of these tumors and 80% to 90% are detected before the end of the second year after birth.[1]

If the lymphangioma is part of a generalized disorder with cystic involvement of many organs and tissues the term systemic cystic angiomatosis is used.

Different organs have been involved including mesentery, liver, spleen, kidney, lung, mediastinum, pericardium, skeletal system, and somatic soft tissue. The clinical presentation varies depending on which organ system is involved.[1, 2] Patients with splenic lymphangioma could be asymptomatic or symptomatic at the time of diagnosis. The most common symptom is left upper quadrant pain as a result of enlarging abdominal mass. Other signs and symptoms include nausea, vomiting, weight loss, hypertension, hypersplenism, and consumptive coagulopathy.[2] This last complication is a result of platelet trapping within an angiomatous cyst. A dramatic resolution of the symptoms is generally observed after surgery.

Our patient had involvement of three visceral organs—kidney, liver, and spleen. The clinical presentation at the time of admission was a result of the splenic involvement of the disease.

The techniques currently in use of the evaluation of the spleen include arteriography, computerized tomography scan, scintigraphy, and ultrasonography. The radionuclide and computerized tomography scan can show splenomegaly with multiple focal defects. A "Swiss cheese" appearance on angiography has been considered pathognomonic of splenic cystic lymphangiomatosis. Sonography is a simple and informative, noninvasive technique that can confirm the cystic nature of the lesion and identify involvement in other organs without the use of dyes or radiation.

The differential diagnosis of cystic diseases of the spleen includes parasitic cysts, epithelial lined cysts, and malignancies. The preoperative workup in our patient was not suggestive of a malignancy, but the final diagnosis can be verified only after surgery.[1]

One advantage of performing the surgery in a controlled situation is the prevention of splenic rupture later in pregnancy. This dangerous complication was first reported in a pregnant woman in 1803 by Saxtorph. Buchsbum reviewed 72 cases of splenic rupture during pregnancy and found that most of the affected patients were multiparous and 60% of the ruptures occurred during the third trimester or intrapartum. The presence of a malformed spleen carries a higher risk for spontaneous rupture. The maternal mortality in his series (15.4%) was a result of delay in diagnosis. The perinatal mortality was 70%, and in all cases of surviving infants the splenic rupture occurred before the third trimester.

The postoperative complications of splenectomy are subphrenic abscess, thrombocytosis, and infection. Abscess formation is more common in patients undergoing splenectomy for trauma. The occurrence of thrombocytosis seems to be related to the underlying disease. Its incidence ranges between 7% to 70%. In general, patients with hypersplenism have a higher risk of this complication. Asplenic patients are also at risk of the development of overwhelming infections. This

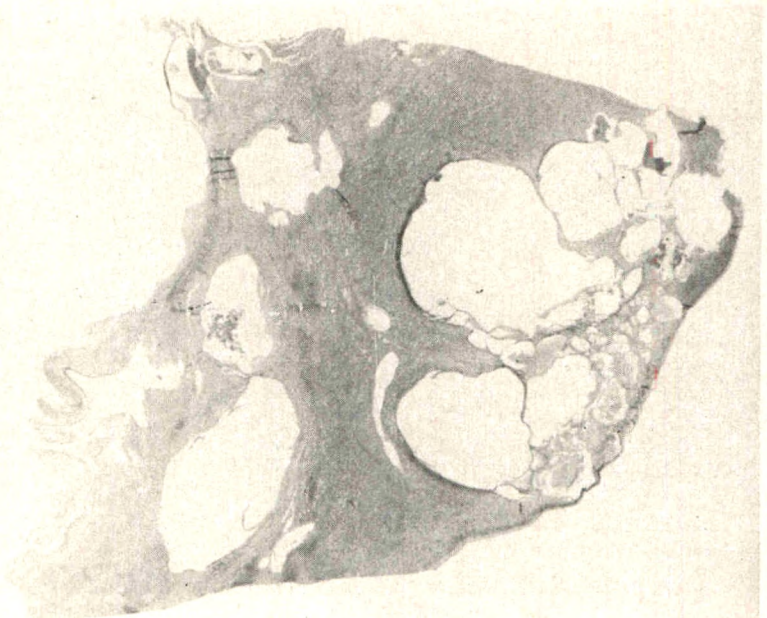

Fig. 2A. Histopathology of spleen illustrates multiple cystic changes on external surface.

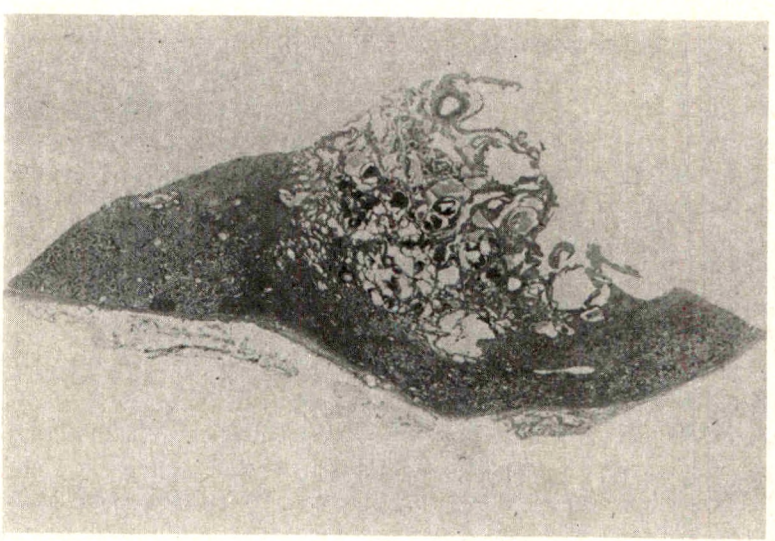

Fig. 2B. Cysts are filled with clear or hemorrhagic fluid compatible with mixed lymphangioma and hemangioma of spleen.

increased predisposition to infection is a result of defective or decreased production of immunoglobulins, a delayed macrophage mobilization, and a defective phagocytosis of pathogenic bacteria. Therefore these patients must be followed up carefully and periodic immunizations should be given as necessary.

Our patient represents a case of symptomatic systemic cystic angiomatosis that was first seen during pregnancy. Sonographic evaluation confirmed the splenomegaly and revealed the cystic nature of that organ. A conservative approach was not advisable because the patient's symptoms worsened during her stay

in the hospital, a benign cause could not be confirmed without tissue pathology, and the possibility of splenic rupture at a more advanced gestational age. It is our belief that the maternal and fetal risks of an emergency splenectomy exceed those of a controlled second-trimester laparotomy.

Interrelationship between atrial natriuretic factor concentrations and acute volume expansion in pregnant and nonpregnant women

Christos G. Hatjis, MD,[a, c] Alexander D. Kofinas, MD,[a] James P. Greelish, BA,[a] Melissa Swain, RN,[a] and James C. Rose, PhD[a, b]

Winston-Salem, North Carolina, and Columbus, Ohio

The secretion of atrial natriuretic factor by human atrial myocytes is stimulated by increased intraatrial pressure or atrial distention. To determine whether acute intravascular volume expansion affects atrial natriuretic factor concentrations during pregnancy, circulating atrial natriuretic factor levels were measured in pregnant women at term (before elective cesarean section) and nonpregnant control subjects before and during intravenous infusion of lactated Ringer's solution (approximately 30 ml/kg). Venous plasma concentrations of α-human atrial natriuretic factor were determined by a specific radioimmunoassay. A significant increase in α-human atrial natriuretic factor levels in nonpregnant subjects was seen. Pregnant women did not show a significant response to a similar stimulus. Finally, basal α-human atrial natriuretic factor levels in pregnant and nonpregnant women were not different. Volume expansion (long-term or short-term) in normal human pregnancy may not be sensed by atrial volume sensors, possibly because it is accommodated by an enlarged maternal vascular compartment. (Am J Obstet Gynecol 1990; 163:45-50.)

Key words: Maternal atrial natriuretic factor concentrations, nonpregnant women atrial natriuretic factor concentrations, volume expansion

Atrial natriuretic factor (ANF) is a hormone secreted by specialized cells in atrial myocytes.[1] ANF demonstrates multiple circulatory and endocrine effects ranging from vasodilation and natriuresis to inhibition of aldosterone and renin production.[2] Increased intraatrial pressure or atrial distention stimulates secretion of ANF. Physiologic or pathologic conditions of central hypervolemia that are secondary to intravascular volume expansion may result in increased secretion of ANF and high circulating levels of α-human ANF (α-hANF).[2]

We have previously shown that during normal human pregnancy maternal ANF levels do not change with advancing gestation.[3] This lack of increase in the maternal plasma ANF concentrations occurs despite a presumed increment in plasma and blood volume during pregnancy. We therefore asked the question whether normal pregnant women at term can respond to an acute intravascular volume expansion with an increase in circulating maternal α-hANF levels and whether there is a difference between their response and that seen in nonpregnant control subjects.

Material and methods

Patient population. The study was approved by the Clinical Research Practices Committee at the Bowman Gray School of Medicine. All patients signed an informed consent form. There were eight patients at term who were studied before elective cesarean section. There were five nonpregnant subjects who were studied in the proliferative phase of the menstrual cycle. All patients were studied in the morning (7 to 11 AM). They had nothing to eat or drink since the night (10 PM) before. All subjects were normotensive and had no previous history of cardiovascular or renal disease. They were taking no medications except iron and prenatal vitamins (pregnant women). None of the pregnant women were in labor. All underwent cesarean sections while they were under conduction anesthesia.

Volume challenge. In pregnant women who underwent epidural anesthesia, injection of the local anesthetic did not commence until ≥25 minutes. A satisfactory block at the T4 level was achieved by 50 to 60 minutes. Nonpregnant subjects did not undergo conduction anesthesia. All patients were in the left or right lateral decubitus position during the fluid infusion and subsequent observation. We used lactated Ringer's solution as the crystalloid solution for the intravenous volume expansion. For time 0 to 25 minutes, lactated Ringer's solution was infused rapidly. The rate of infusion was 92.5 ± 8.8 ml/min for the pregnant group and 99.3 ± 15.9 ml/min for the nonpregnant group (mean ± SD, differences not significant). The rate of infusion was then tapered off for the remainder of the sampling period.

Blood collection. Venous blood was obtained through an indwelling 19- to 20-gauge catheter and was immediately placed in prechilled ethylenediaminetetraacetic acid containing tubes. The indwelling catheter had been inserted in the arm opposite to the one where the intravenous site was located. Approximately 5 to 10 ml of blood was obtained at various times before and during the intravenous fluid infusion for analytic studies. Blood was kept on ice. Plasma was separated by centrifugation at 4° C and stored at −40° C until analyzed. Under these conditions no significant loss of ANF was noted.

ANF assay. ANF in plasma samples was extracted by a procedure initially described by Brier et al.[4] and validated in our laboratory.[5] A total of 1 ml of plasma and 1.5 ml of 0.1 mol/L acetic acid were mixed. Methanol (2.5 ml) was then added to the extraction tube, and the contents were mixed for 10 minutes. The tubes were then centrifuged at 6000 rpm at 4° C for 20 minutes. The supernatant was poured into a new tube containing 2.5 ml of chloroform and mixed with total inversion for 10 minutes. The tubes were again centrifuged as before. The top (aqueous) layer was removed to a new tube and lyophilized. The extracted samples were stored in −40° C until assayed. They were then allowed to thaw and reconstituted before the assay with 1 ml of 80 mmol/L phosphate buffer (pH 7.4). With this procedure recovery of unlabeled ANF was 54% ± 3%. Recovery was routinely monitored in every assay.

Samples and standards were incubated for 24 hours at 4° C with 100 μl of anti-α-hANF antibody obtained from Dr. Kozo Hashimoto (Department of Internal Medicine, Okayama University Medical School, Okayama, Japan) in 80 mmol/L phosphate buffer (pH 7.4). α-hANF labeled with iodine 125 (5000 to 10,000 cpm/tube) was then added and the tubes were incubated for an additional 24 hours. The antigen-antibody complex was then precipitated with 100 μl of goat antirabbit immunoglobulin G and 100 μl of normal rabbit serum. These tubes were then incubated for 2 hours at room temperature. Phosphate buffer was added and the tubes were centrifuged for 20 minutes at 1500 *g*. The supernatant was decanted and the dried pellets were counted for 5 minutes in a γ-counter. Synthetic α-hANF (Peninsula Laboratories, Belmont, Calif.) (3 to 1000 pg/tube) was used to construct the standard curve. All samples were assayed in duplicate while the standard curve was done in triplicate. The interassay coefficient of variation ranged from 10% to 14% and the intraassay variation was between 6% and 8%. Results were analyzed by means of a four-parameter logistic equation.[6] The 50% inhibitory concentration ranged from 40 to 50 pg/tube. The results are expressed as picograms per milliliter and have been corrected for percent recovery. The conclusions drawn for these results are the same regardless of whether the concentrations have been corrected for the extraction efficiency.

Determinations of serum osmolality and blood hematocrit. Serum osmolality was determined by freezing point depression.[7] The determination of hematocrit was done by the microhematocrit method.[8]

Statistical analysis. Results are presented as mean ± SEM, unless otherwise noted. Statistical analysis was carried out by analysis of variance (repeated measures) and Newman-Keuls test. A value of $p < 0.05$ was considered as significant.

Results

Table I shows selected clinical parameters for the two groups. The two populations of women were similar with regard to age and reproductive history. Although the total volume infused was greater in the pregnant women than in the nonpregnant women when volume was corrected for the subject's body weight, both groups received equivalent volumes of crystalloid. All pregnant women were delivered at term of appropriate-for-gestational-age infants. There were no antepartum intrapartum, or postpartum complications. Seven patients received epidural anesthetics and one patient received a spinal anesthetic. Since a Foley catheter had not been placed in any of these patients, no urine output or solute excretion results are available.

Table II shows ANF concentrations before and after intravenous volume expansion. Basal ANF concentrations in pregnant and nonpregnant women at time 0 were not different. Acute volume expansion with infusion of lactated Ringer's solution resulted in a significant increase in ANF concentrations in nonpregnant subjects only (≥20 minutes compared with time 0). In contrast to the above, pregnant women did not show a significant response to a similar stimulus. The fact that the increase in ANF levels in nonpregnant subjects was first seen at 20 minutes makes it unlikely that conduction anesthesia was a significant confounding variable at that point since the epidural anesthetic was not injected until after 25 minutes. Finally, for times ≥15 minutes, ANF concentrations in the nonpregnant women were higher than those in the pregnant subjects.

Table III shows serum osmolality before and during intravenous volume infusion. As determined in our laboratory, there were no significant differences in serum osmolality between the pregnant and nonpregnant groups of women. This was the case both before and during the intravenous volume infusion.

Table IV shows hematocrit levels before and during intravenous volume infusion. Hematocrit levels at 20 and 50 minutes after the start of the infusion were significantly lower than those seen at time 0. This was true for both the pregnant and nonpregnant groups. Mean arterial blood pressure did not change appreciably during the intravenous infusion (Table V). However, heart rate before and during intravenous volume infusion changed significantly for the pregnant subjects only. There was a significant, albeit moderate, increase in heart rate at 20 and 50 minutes after the start of infusion (Table VI). Since the pregnant subjects had not received the epidural anesthetic at 20 minutes, there is no plausible explanation for this minor increase in maternal heart rate, whereas at 50 minutes peripheral vasodilation might explain the change. Fetal heart rate remained in the normal range throughout the study.

Comment

One of the major physiologic adaptations to pregnancy is the expansion of intravascular and extracellular fluid volume.[9] The underlying mechanisms responsible for this remarkable change are not understood. In an attempt to evaluate the physiologic significance of ANF to human pregnancy and determine whether it is involved in the regulation of the marked volume changes that occur during pregnancy, we have asked the following question: Does long-term

Table II. ANF concentrations before and after intravenous volume infusion

	0 min	*5 min*	*10 min*	*15 min*	*20 min*	*30 min*

or short-term volume expansion affect circulating maternal ANF levels? We have previously reported that long-term volume expansion that occurs during normal human pregnancy does not appreciably change maternal ANF levels.[3] We present data on the changes in ANF levels after acute volume expansion at term.

This is the first instance where the response in ANF concentrations to an acute volume stimulus was studied

40 min	*50 min*
88.05 ± 5.83	87.37 ± 6.48
(n = 7)	(n = 6)

in pregnant women at term and was compared with that seen in nonpregnant subjects. We selected patients who were to undergo an elective cesarean section at term while under conduction anesthesia for several reasons. These patients were not in labor and had no complications. They *would have* normally received a volume stimulus, of the magnitude described in the Material and methods section, in the routine course of preanesthesia volume expansion. Thus our study presented *minimal* risk to the patients and their fetuses. Although we did contemplate the measurement of intravascular volume in these subjects, our institutional review board felt that the benefits did not outweigh the potential risks. As a result no intravascular volume studies were performed. Thus volume infusion was based on estimates derived from the subjects' body weights. We did not use a Foley catheter to evaluate urine and electrolyte outputs because the question this study was designed to answer was limited to the effects of an exogenous intravenous fluid bolus on venous ANF concentrations. Moreover, the institutional review board felt that for the nonpregnant subjects a Foley catheter might have represented more than minimal risk.

The major part of volume expansion took place during the first 20 minutes of the study period, during which time the epidural anesthetic had not been injected. After 25 minutes local anesthetic was injected in the epidural catheter, and an adequate level of anesthesia was achieved by 50 to 60 minutes from the start of the infusion (one patient received a spinal anesthetic). Nonpregnant subjects did not undergo conduction anesthesia. We have found that nonpregnant women showed a significant increase in ANF levels as early as 20 minutes after the start of the fluid infusion. In contrast, pregnant women did not show an appreciable increase in ANF concentrations. Thus, during the time that the local anesthetic had not been injected (<20 minutes), ANF levels did not increase in pregnant women, but they did increase significantly in the nonpregnant group. However, beyond the 25-minute point, the lack of ANF response in the pregnant group might be partially accounted for by the vasodilation occurring in association with the epidural anesthetic. The latter would have resulted in intravascular space expansion and could conceivably have blunted the response.

Given these considerations, our observations suggest that circulating maternal plasma ANF concentrations do not increase as a result of a substantial *short-term* volume load. This response is different from that seen in nonpregnant human subjects or in pregnant ewes.[10] Finally, we have confirmed our previous observations that there is no difference between maternal ANF concentrations during pregnancy and those seen in nonpregnant subjects.[3]

No significant changes in serum osmolality were noted at the three time points we had selected as our sampling points. This rules out any potential effects of changes in serum osmolality on ANF secretion. In contrast, hematocrit levels did decrease, albeit very modestly. The latter is consistent with intravascular dilution.

Although mean arterial blood pressure did not change as a result of the infusion, interestingly, maternal heart rate increased at 20 minutes and increased further at 50 minutes after the start of the infusion. This observed increase apparently did not have any impact on maternal ANF concentrations. It has been reported that marked ventricular tachycardia might stimulate ANF secretion.[11]

From this study of acute volume expansion we conclude that in normal pregnancy an intravascular volume increase may not be sensed adequately by atrial volume sensors. This is in contrast to nonpregnant women who did show a significant increase in circulating ANF levels as a response to a comparable intravenous volume stimulus. This lack of response in circulating ANF concentrations in pregnant women to a significant intravenous volume stimulus could be due to an enlarged maternal vascular compartment during pregnancy. The latter might have prevented a significant increase in intraatrial pressure and volume. Noninvasive or invasive hemodynamic studies might have to be carried out to provide a partial answer to that question. Finally, increased ANF clearance might be partially responsible for this lack of response during pregnancy. Further studies will be necessary to determine the contribution of these potential variables.

In utero detection of cardiac failure from an aneurysm of the vein of Galen

Philippe Jeanty, MD, PhD,[a] Donna Kepple, RDMS,[a] Pericles Roussis, MD,[b] and Dinesh Shah, MD[b]

Nashville, Tennessee

The detection of a vein of Galen aneurysm in a hydrocephalic fetus is presented. The differential diagnosis for the midline cystic structure was made on the basis of the presence of high-velocity flow on Doppler ultrasonographic examination. (Am J Obstet Gynecol 1990;163:50-1.)

Key words: Abnormalities, multiple diagnosis, prenatal diagnosis, ultrasonographic diagnosis, vein of Galen aneurysm

The vein of Galen aneurysm is the generic name for midline arteriovenous fistula malformations associated with aneurysmal dilatation of the vein of Galen.[1] The common clinical features in the neonate are cardiomegaly with congestive heart failure and increased intracranial pressure with hydrocephaly or cranial bruit. When the associated intracranial abnormality is not recognized, unnecessary cardiac examinations are performed that delay the diagnosis and treatment. Because the diagnosis of the fetal-neonatal form is almost pathognomonic, we present a case that illustrates the pertinent findings.

Case report

A 24-year-old gravida 2, para 1-0-0-1 patient was referred to us because an examination performed by her obstetrician revealed hydrocephalus. On examination there was no dilatation of the ventricular system, but a midline cystic structure was present that extended posteriorly in the direction of the straight sinus (Fig. 1). Marked enlargement of the vessels of the polygon of Willis, sigmoid sinus, common carotid arteries, jugular veins, superior vena cava, and main pulmonary artery and ductus was noted. The heart was remarkable for the enlargement of the right cavities, as compared with the left. The foramen flap bulged in the left atrium without the usual flapping. The newborn was born at term. He was treated with embolization of the fistula by coils[2] that were complicated by intracranial hemorrhages and seizures. He died of cardiac failure at 6 months of age.

Comment

Asymmetry of the cardiac chambers is an unusual finding in utero. In this case the large excess flow exceeded the capacity of the natural right-to-left shunts. The classic appearance of the varix is of a midline hypoechoic structure. The denomination of aneurysm of the vein of Galen includes different arteriovenous fistulae located in the vicinity of the midbrain that vary from a single large aneurysmal dilatation of the vein

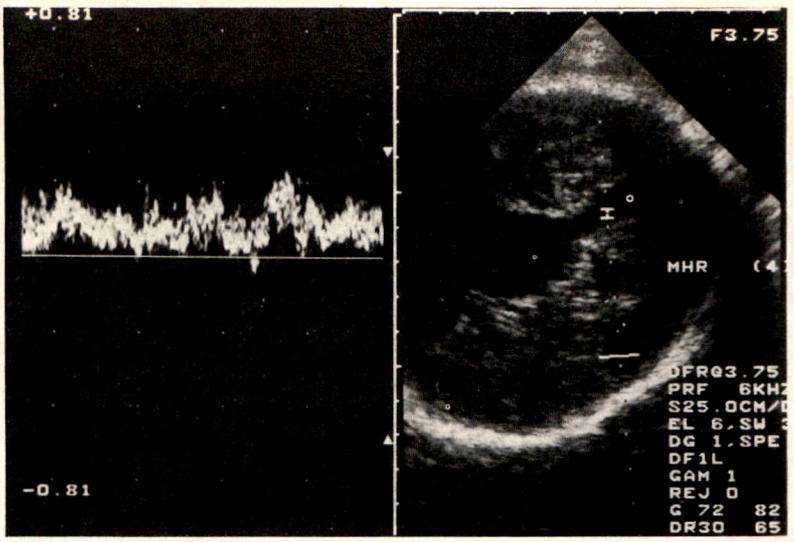

Fig. 1. Doppler ultrasonography and two-dimensional examination of the aneurysmal dilatation of the vein of Galen. Volume sample is placed in draining vessel that exhibits a large amount of low-resistance turbulent flow.

of Galen to multiple communications between the vein and the carotid and vertebrobasilar systems. The most common types are the arteriovenous fistula of the vein of Galen, a cerebral arteriovenous malformation with ectasia of the vein of Galen, or a varix of the vein of Galen. Aside from congestive heart failure, the shunt can also create hydrocephalus by compression of the aqueducts, a steal phenomenon that is responsible for parenchymal loss or atrophy, and decrease or absence of short- and long-term heart variability because of cerebral hypoxia. Pineal malformation may also result from the compression and the steal phenomenon.

There are very few anomalies that can appear as a midline cystic structure. The most likely, of course, is an arachnoid cyst. Far less likely diagnoses include coloid cysts, choroid plexus cysts, porencephalic cysts, pineal tumors, intracerebral hematoma, and choroid papilloma. What is unique in the vein of Galen aneurysm is the presence of high-velocity flow on the Doppler examination. None of the other differential diagnoses should present any such flow. The recognition of cardiomegaly (especially at the expense of the right side) and the detection of the massively distended jugular vein establish the diagnosis.

Morphologic study of changes of collagenous tissue in the amnion and cervix during prostaglandin-induced abortion and delivery

Yukio Manabe, MD, and Yoshinobu Yoshida, MD
Kyoto and Shiga, Japan

Marked dissociation of the cervical collagenous tissue during prostaglandin-induced abortion is well recognized, but the response of collagenous tissue of the amnion to prostaglandin treatment is not known. A morphologic study of amniotic collagenous tissue was performed after prostaglandin-induced abortion and prostaglandin-induced term delivery. The collagenous fibers of the amnion were found to be closely packed with no ground substances and formed in a thick layer. Cervical collagenous tissue of the same patients showed a marked dissociation of fibers and abundant ground substance. The fetus was often delivered within a complete sac at midtrimester. These findings suggest differences in collagenous tissue responses to prostaglandin treatment between the amnion and cervix. (Am J Obstet Gynecol 1990;163:52-6.)

Key words: Collagenous tissue, amnion, cervix, prostaglandins

Prostaglandins (PGs) delivered by various routes can ripen the cervix either in the nonpregnant state or during pregnancy. The histologic appearance of the cervix in PG-induced abortion shows the changes found in the cervix at term. The collagenous tissue shows marked dissociation of fibers and the amount of ground substance is increased.[1, 2]

The amniotic membrane also consists of collagenous connective tissue. Although the collagenous tissue of the amnion is extremely thin,[3] it plays an important role in the resistance of the amnion to premature rupture during normal pregnancy.[4] Our morphologic study showed that collagenous tissue in the human amnion, in contrast to that in the cervix, was not dissociated and had no ground substance when examined during normal pregnancy and delivery.[3]

In PG-induced abortion we often find that, despite marked cervical softening and nonphysiologically strong uterine contractions, the fetus is delivered within a complete sac. This is also noted in pure stretch-induced abortion,[3] and there is no marked difference between the two.

In this study we morphologically compared collagenous tissue and fibroblasts of the amnion with those of the cervix after PG-induced abortion and delivery.

Material and methods

Samples of the amnion and cervix were collected from 24 normal women at different stages of pregnancy: during midtrimester between 13 and 16 weeks ($n = 8$), between 17 and 21 weeks ($n = 8$), and at the end of pregnancy between 38 and 41 weeks' gestation ($n = 8$). None of the patients had any evidence of infection, judging from body temperature and plasma levels of C-reactive protein. No limitations were placed on the age or parity of the patients.[3] The purpose and nature of the study were explained to each patient and their written consent was obtained.

For abortion at midtrimester, vaginal suppositories that contained 1 mg of a PGE_1 analog (Pregrandin, Ono Pharmaceutical Co., Japan) were inserted into the posterior fornix.[5] For the induction of labor at term, the intravenous infusion of a PGF analog (Prostarmon-F, Ono Pharmaceutical) was used.

Immediately after placental delivery, discs of fresh amniotic membrane were excised from the placental and reflected regions. They were processed as described previously[3] for light and electron microscopic examination. Cervical samples were obtained from the same patients. Small wedge-shaped biopsy specimens were taken from two points: (1) approximately 1 cm from the squamocolumnar junction and (2) from the glandular region.

The biopsy specimens for morphologic study were

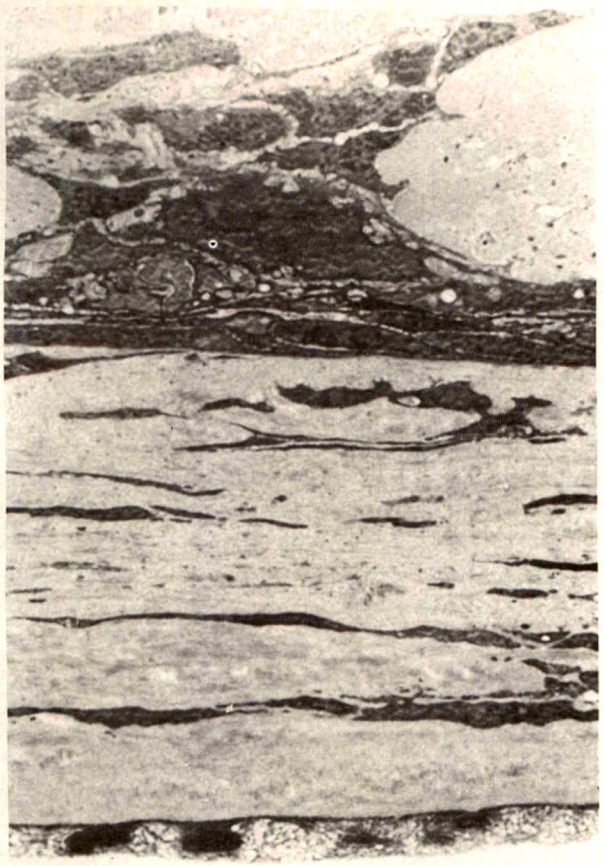

Fig. 1. Amnion from patient with prostaglandin-induced abortion (21 weeks' gestation). From top to bottom, epithelium, collagenous tissue, in which fibroblasts are intermingled, and trophoblastic layer are observed. Collagenous fibers are compact and densely packed. No leukocyte infiltration is observed. (Sections from material embedded in Epon plastic, stained with toluidine blue. Original magnification ×600.)

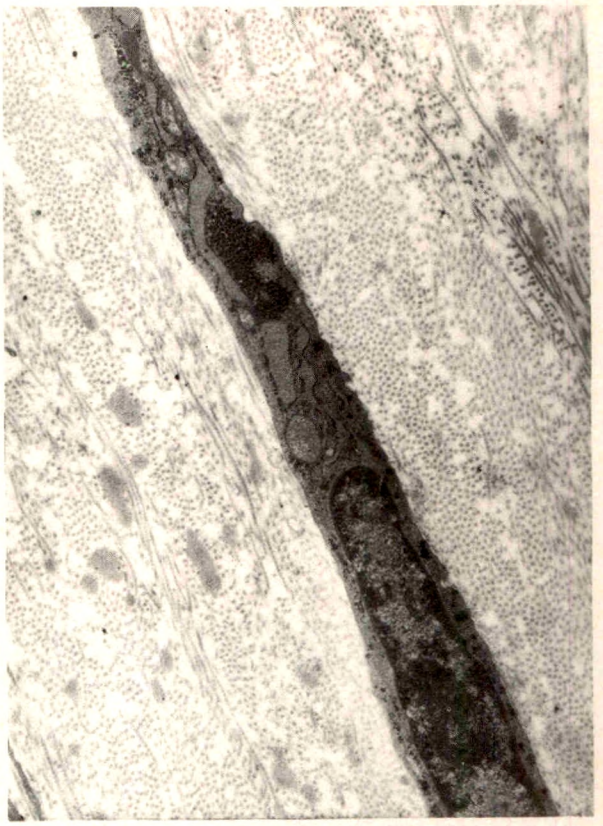

Fig. 2. Electron micrograph of fibroblast layer of amnion from same patient as shown in Fig. 1. Collagen fibrils are regularly oriented and compact. Amorphous ground substance is not noted. Fibroblast shows massive accumulation of glycogen granules and few vesicles located close to plasma membrane. In this case fetus was delivered within unruptured sac. (Original magnification ×11,800.)

immediately fixed with 2% paraformaldehyde in 0.1 mol/L sodium cacodylate buffer (pH 7.4) with 0.25 mol/L sucrose at 0° C to 4° C for 12 hours. After fixation the specimens were embedded in paraffin, sectioned, and stained by the hematoxylin-eosin, Gomori trichrome, and Sudan III methods.

The other specimens were fixed with 2% glutaraldehyde in 0.1 mol/L cacodylate buffer (pH 7.4) with 0.25 mol/L sucrose at 0° C to 4° C for 3 hours. The subsequent processing was as has been previously described.[3] Ultrathin sections were observed under a Hitachi H-500 electron microscope. Also sections 1 μm thick from specimens embedded in Epon plastic for the electron microscopic study were stained with toluidine blue and observed under a light microscope.

The thickness of the amnion was determined by light microscopy of vertical sections.

Results

Fig. 1 shows a light micrograph of the amnion obtained after prostaglandin-induced abortion at 21 weeks' gestation. The amnion under the epithelium had a more homogenous and compact collagen layer than that of the cervix, regardless of the stage at which the sample was obtained. The amorphous ground substance was absent. The thickness of the amnion ranged from 0.08 to 0.12 mm and did not vary significantly among the specimens. No leukocyte infiltration was noted in any of the specimens.

Fig. 2 shows an electron micrograph of connective tissue in the amnion from the same patient as shown in Fig. 1. The collagenous tissue was dense and composed of a vast number of collagen fibers embedded in a matrix of low density. Fine granular or amorphous ground substance was not seen. Ultrastructurally, fi-

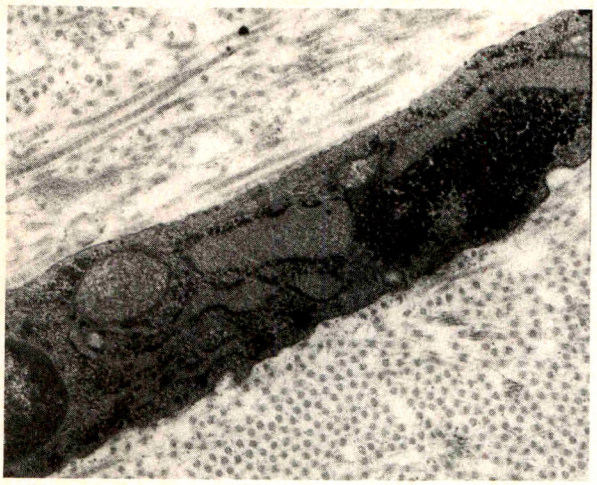

Fig. 3. Higher magnification of fibroblast shown in Fig. 2. Marked glycogen deposition and few pinocytotic vesicles are visible. (Original magnification ×23,000.)

Fig. 4. Cervix from same patient as shown in Fig. 1. Collagen fibers are markedly dissociated, and edema and ground substances are increased compared with those of amnion. No leukocyte infiltration is observed. Specimen was taken 1 cm from squamocolumnar junction. (Section from material embedded in Epon plastic, stained with toluidine blue. Original magnification ×600.)

broblasts contained marked glycogen deposition and occasional pinocytotic vesicles; these findings were similar in all specimens studied (Fig. 3).

At a higher magnification (Fig. 3), the amnion exhibited regularly oriented and closely interwoven collagen fibrils, about 50 nm in diameter. The fibrils showed a periodicity of approximately 60 nm, which is typical for collagen. The densely packed collagen fibrils showed no sign of splitting or dispersion, and the absence of amorphous ground substance was characteristic. The compact arrangement of the collagen fibrils did not vary with the stage of pregnancy.

Light microscopy of the cervix (Fig. 4) revealed marked edema in all specimens, as evidenced by the many clear spaces observed between individual collagen fibers. The collagen fibers were clearly more dispersed and the ground substance was markedly increased compared with those of the amnion. Increased vascularity and the presence of dilated blood vessels were noted regardless of the site of biopsy. Leukocyte infiltration was not observed when the specimen was taken 1 cm from the squamocolumnar junction but leukocyte infiltration was noted in specimens taken from the glandular region (i.e., inside the squamocolumnar junction).

The electron microscopic appearance of the cervix markedly differed from that of the amnion. During pregnancy (Fig. 5) and at term the collagen fibers (i.e. the bundles of fibrils) were sparse and less regularly oriented than those in the amnion. Abundant deposits of amorphous ground substance were commonly present between the fibers. Ultrastructurally, the fibroblasts, in comparison with those in the amnion, contained fewer glycogen granules and a markedly larger number of vesicles close to the plasma membrane and of invaginations of the membrane (Fig. 6). The findings were similar in all specimens.

At a higher magnification (Fig. 6), the dispersion at the collagen fibers was more clearly visible. The gaps between the fibers were increased, although the fibrils still had periodic bands of approximately 60 nm as in the case of the amnion. Amorphous ground substance around the collagen fibers and fibrils was far more abundant than that in the amnion. The same dispersed collagen arrangement and abundance of ground substance were noted in all specimens.

During PG-induced abortion at midtrimester (13 to 22 weeks' gestation), of a total of 16 patients there were 11 fetal deliveries with unruptured sacs or with rupture of the membranes protruding out of the vagina. In the majority of term patients, rupture of the membranes usually occurred when the cervix was more widely dilated than on abortion at midtrimester.

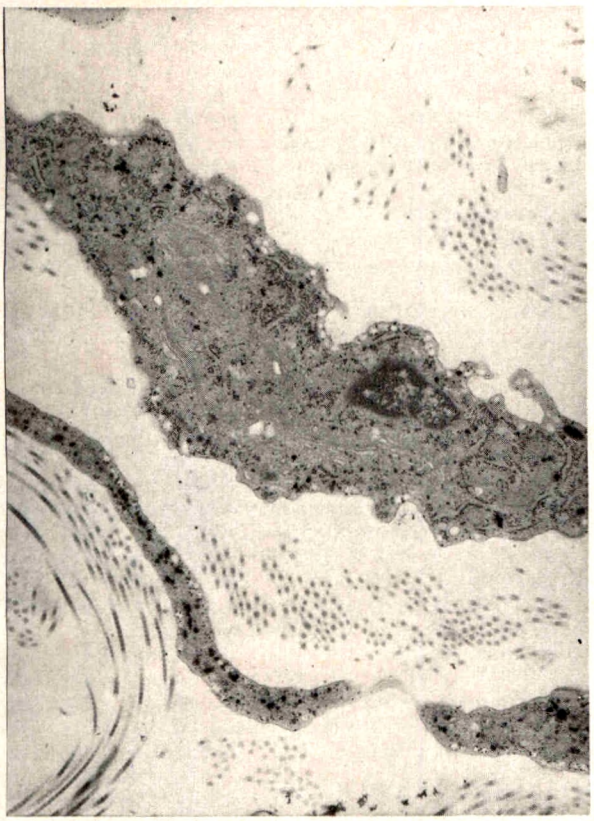

Fig. 5. Electron micrograph of cervix from same patient as shown in Fig. 1. Collagenous fibers are dissociated and abundant amorphous ground substance is present, which appears as dark areas in photograph. Fibroblast has many vesicles located close to plasma membrane, and few glycogen granules are seen. (Original magnification ×11,800.)

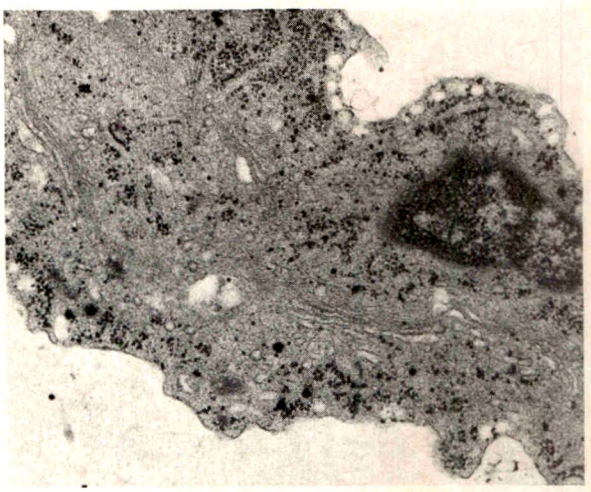

Fig. 6. Higher magnification of fibroblast shown in Fig. 5. Many vesicles close to plasma membrane and few glycogen granules are observed. (Original magnification ×23,000.)

Comment

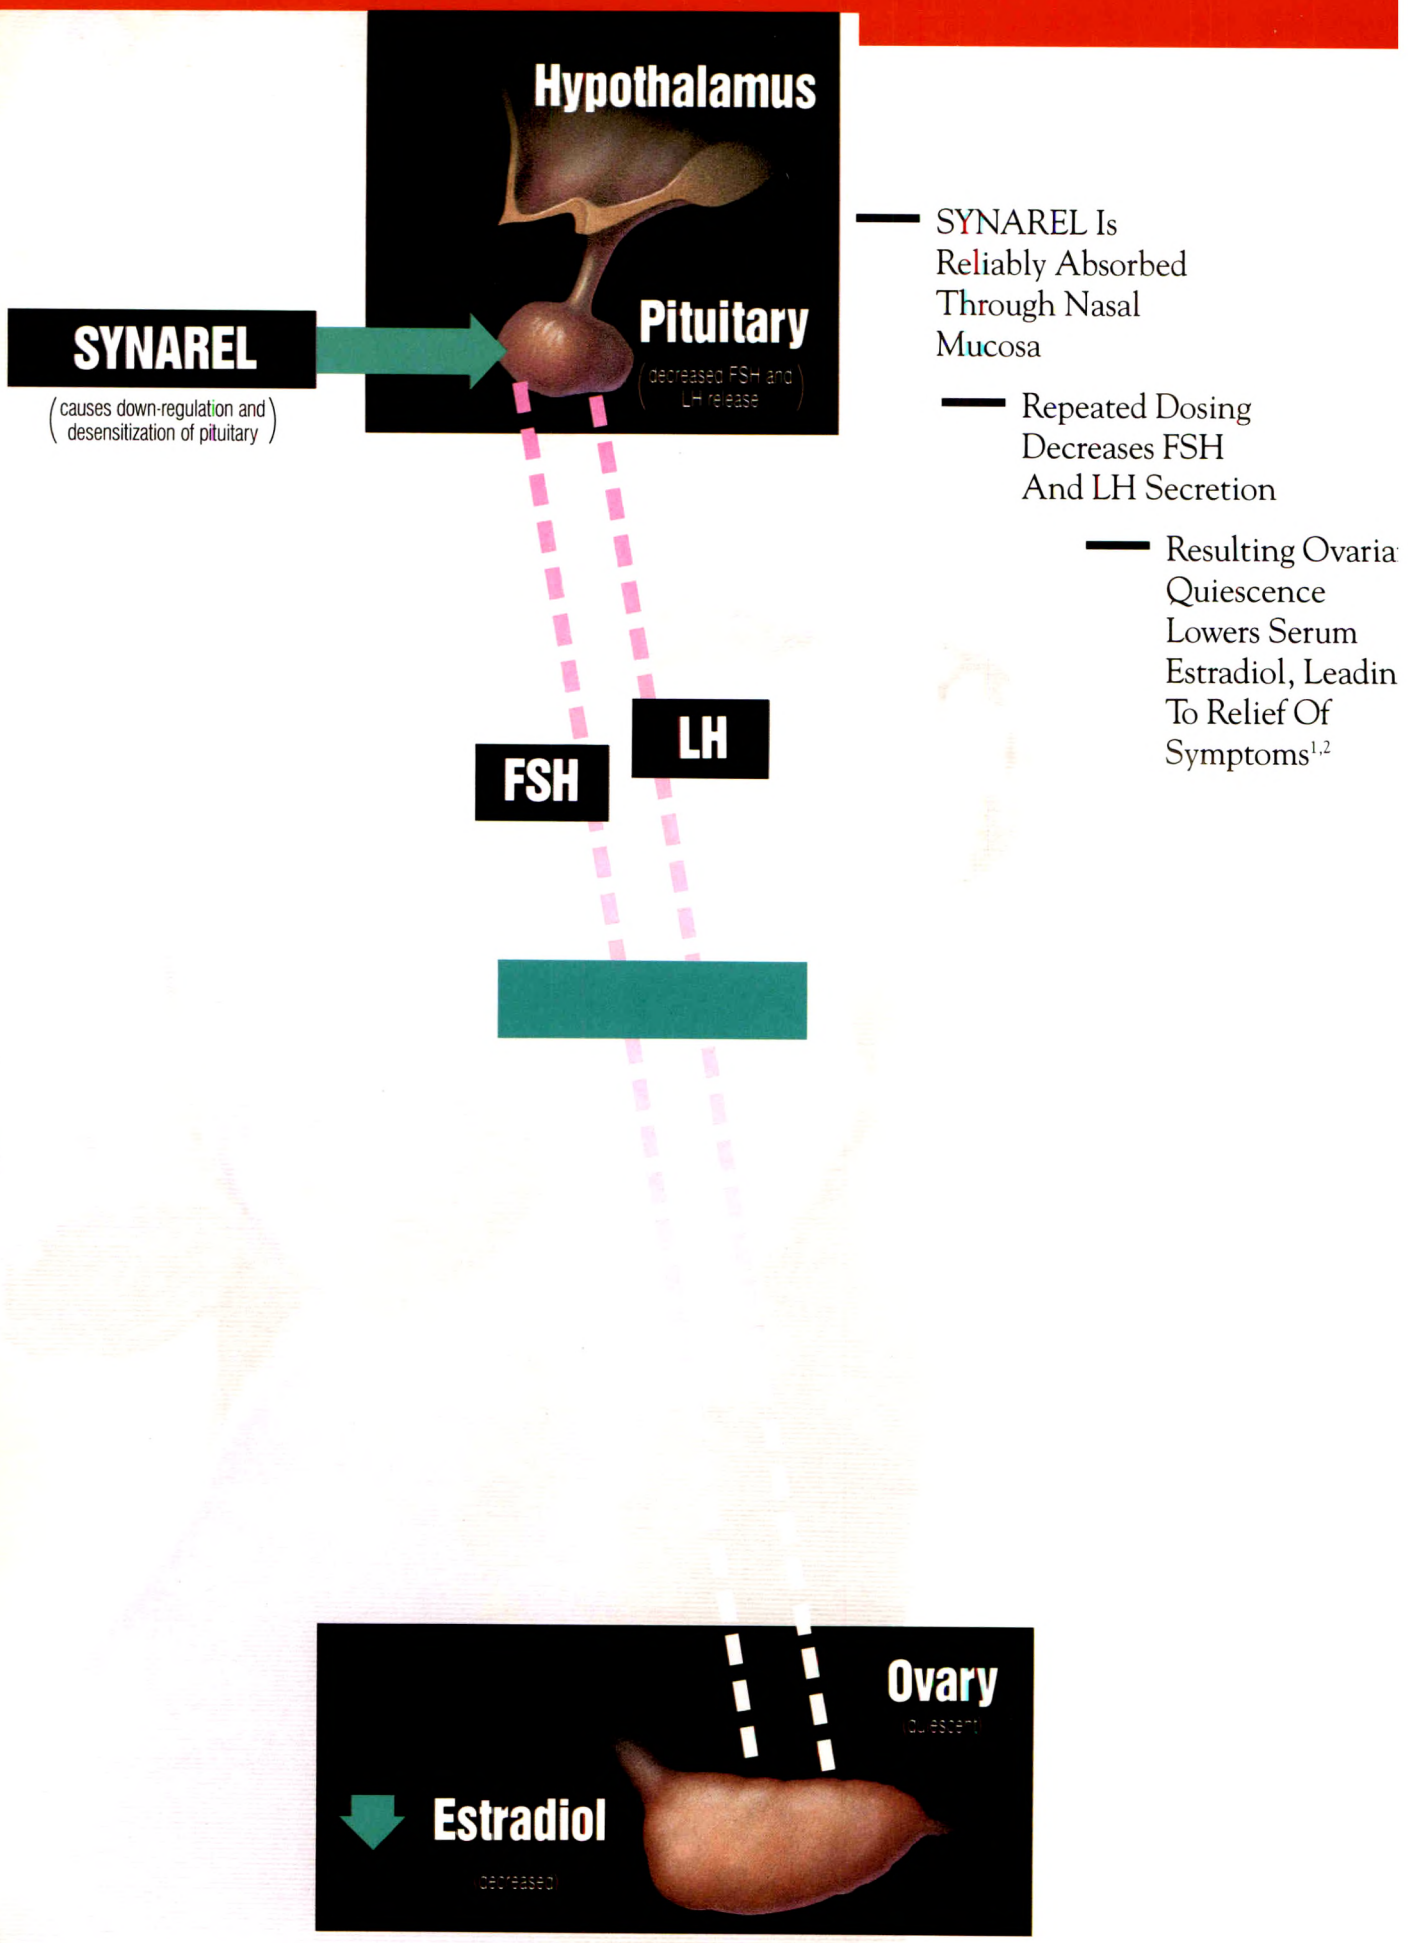
The present findings histologically showed that the response to PG treatment of collagenous tissue in the amnion is different from that in the cervix. In PG-induced cervical ripening, tissue collagenase levels increase[6] or are unchanged.[7] The amount of tissue collagen is unchanged[1] or decreases.[8] A significant increase in the concentration of sulfated glycosaminoglycans has been noted in the cervix after PG treatment.[1] PGs have been shown to stimulate synthesis of proteoglycans in cultured fibroblasts[9] and in the human uterine cervix under in vitro conditions.[10] The increase of the amorphous substance between collagenous fibers in the PG-treated [1,2] and intrapartum cervix[11] is thought to be assoicated with the newly synthesized proteoglycans.

The present findings showed that the amniotic collagen apparently resisted tissue dissociation and weakening in PG-induced abortion. Both histologic evidence and the clinical findings that the fetus often was delivered within an intact sac despite strong uterine contractions support this conclusion. Because no ground substance was noted among the collagen fibers, PGs do not appear to activate fibroblasts in the amnion to synthesize ground substances (i.e., proteoglycans). Also, because there was no dissociation of collagen fibers, the amniotic collagenous tissue appeared not to contain active collagenase. Biochemical studies to clarify these points are in progress. The resistance of the amnion to tissue decomposition by exogenous PGs is in agreement with the same property of the tissue noted during stretch-induced abortion and at normal term delivery[5]; endogenous PG production is known to increase on the former[12] and latter occasions.

Differences in the fibroblasts from the amnion and the cervix were noted. Cervical but not amniotic fibroblasts seemed to be activated as shown by the large number of cytoplasmic vesicles (pinocytotic vesicles) located close to the cell membrane, as has been previously noted by others.[1,2] Fibroblasts in the amnion and cervix seemed to have different characteristics. We found that glycogen granules increase in many fetal cells in a similar manner to those in the amniotic fibroblasts, but the implications of this phenomenon are not clear.

The reason for the different characteristics of collagenous tissue in the amnion and cervix is not clear, but it could be because of the different embryologic origins of these tissues. Collagenous tissue in the amnion is derived from the extraembryonic somatopleuric mesoderm and that in the cervix is of intraembryonic origin.

There has been discussion of the role of leukocyte



factors in the softening of the cervix.[11] We have reported that intrapartum leukocyte infiltration in the cervix is localized to the glandular region in normal pregnancy, whereas the major part of the cervix covered by squamous epithelium[3] and the vagina[13] remain without leukocyte infiltration. Previous analysis of cervical collagenous tissue by other investigators has not shown evidence of leukocyte infiltration caused by PG treatment,[2,7] and our present findings coincide with the previous reports. In the amnion, marked leukocyte infiltration was not noted in stretch-induced and normal term delivery,[3] similar to the present results for PG treatment.

There has been a great deal of discussion of the role of perinatal infections as an etiologic factor in the preterm rupture of the membranes and preterm labor.[14] Extrapolation of these abnormal conditions to normal uninfected term delivery is difficult according to our research.[3] It is also difficult to associate premature rupture of the membranes with increased intrinsic PG elaboration by leukocytes because the collagenous tissue of the amnion resists PG treatment. Nevertheless, neutrophils are a well known source of collagenase[15] and PGs.[16] A light and electron microscopic study is in progress on collagenous tissue of the amnion and cervix in cases of severe infection.

New SYNAREL® For Endometriosis
(NAFARELIN ACETATE)

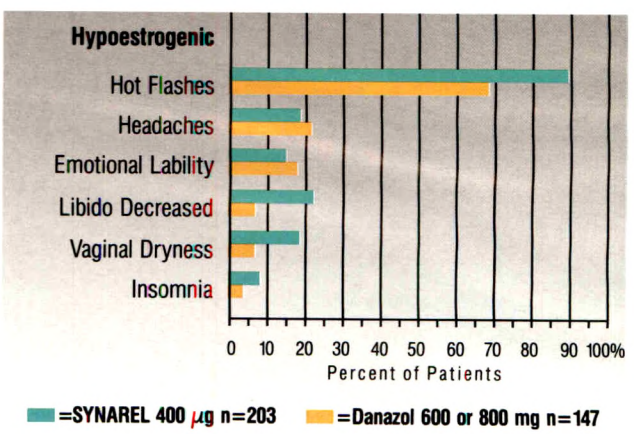
Lowers Estrogen Without Adding Androgens[1, 2]



Synarel Exhibits Fewer Masculinizing Side Effects Than Danazol

Adverse events during 6 months treatment

- More frequent and/or severe with danazol:
  Weight gain
  Edema
  Acne
  Oily skin
  Hirsutism
- Some androgenic effects of danazol—such as voice deepening—may be irreversible[3]
- Patients should be advised to use non-hormonal methods of contraception when taking SYNAREL

Synarel Exhibits Predictable Hypoestrogenic Profile

Adverse events during 6 months treatment

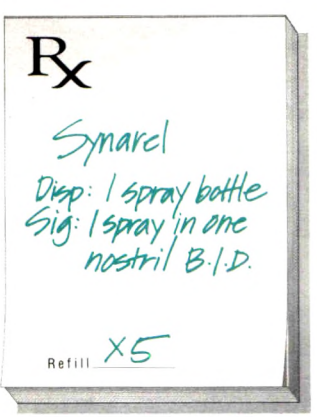
- Estrogen levels return to normal after cessation of therapy
- Bone changes largely reversible 6 months post-treatment

Bone Density Changes During And After Treatment With SYNAREL (400 μg/day)

Site Method Units	Time of Study Baseline	End of Treatment	Post-treatment
Lumbar Vertebrae QCT,* Integral (g/vertebrae) n=21	13.4	12.8 −4.3%	13.1 −3.3%
Trabecular Bone of Vertebrae QCT* (mg/cc) n=23	161.3	147.6 −8.7%	152.0 −4.9%
Lumbar Vertebrae DPA† (g/cm^2) n=6	0.98	0.93 −5.9%	0.96 −1.4%
Distal Radius SPA** (Units) n=6	40.2	39.5 −1.6%	39.6 −0.8%

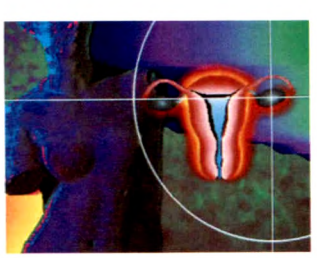
Percent changes from baseline

*Quantitative computed tomography
†Dual photon absorptiometry
**Single photon absorptiometry



Intranasal Administration

Synarel Is The Only GnRH* Agonist Administered Intranasally



B.I.D. controlled-dose administration offers:

- Highly accurate metered-dose delivery—200 µg/spray
- Reliable absorption through nasal mucosa
- Patient convenience with low incidence of nasal irritation (10%)

BRIEF SUMMARY

SYNAREL® Nasal Solution contains nafarelin acetate (2 mg/mL, expressed as nafarelin base), benzalkonium chloric glacial acetic acid, sodium hydroxide or hydrochloric acid, sorbitol, and purified water.

INDICATIONS AND USAGE: For management of endometriosis. Experience is limited to women 18 years and old treated for 6 months.

CONTRAINDICATIONS: Hypersensitivity to GnRH, GnRH agonist analogs or any excipients in SYNAREL; undia nosed abnormal vaginal bleeding; pregnancy or possibility of pregnancy while taking the drug because SYNAREL ma cause fetal harm when administered to a pregnant woman. If SYNAREL is used during pregnancy or if the patie becomes pregnant while taking this drug, she should be apprised of the potential hazard to the fetus; use in women wh are breast feeding.

WARNINGS: Safe use in pregnancy has not been established clinically. Before starting treatment pre nancy must be excluded.

When used regularly at the recommended dose, SYNAREL usually inhibits ovulation and stops menstruation. Conti ception is not insured, particularly if patients miss successive doses. Therefore, patients should use nonhormonal cc traception. Advise patients to see their physician if they believe they may be pregnant. If a patient becomes pregnai during treatment, discontinue the drug; apprise patient of the potential risk to the fetus.

PRECAUTIONS Information for Patients: 1. Since menstruation should stop with SYNAREL, the patient shoul notify her physician if regular menstruation persists. Patients missing successive doses may experience breakthroug bleeding.

2. Patients should not use SYNAREL if pregnant, breast feeding, have undiagnosed abnormal vaginal bleeding, or ar allergic to any of its ingredients.

3. Safe use in pregnancy has not been established. Therefore, a nonhormonal method of contraception should b used during treatment. If a patient becomes pregnant during treatment, she should discontinue the drug and consu her physician.

4. Adverse events occurring most frequently in clinical studies are associated with hypoestrogenism. Nasal irritatio occurred in about 10% of patients.

5. Induced hypoestrogenic state results in a small loss in bone density over a 6-month treatment course. Some of thi loss may not be reversible. During one six-month treatment period, this should not be important. In patients with majc risk factors for decreased bone mineral content, i.e., chronic alcohol and/or tobacco use, strong family history c osteoporosis, or chronic use of drugs that can reduce bone mass such as anticonvulsants or corticosteroids, SYNARE may pose additional risk. In these patients risks and benefits must be weighed carefully. Repeated courses of treatmer with GnRH analogs are not advisable in patients with major risk factors for loss of bone mineral content.

6. Patients with intercurrent rhinitis should consult their physician for use of a topical nasal decongestant. If a topica nasal decongestant is required during treatment, it must be used at least 30 minutes after SYNAREL dosing to decreas the possibility of reducing drug absorption.

7. Retreatment cannot be recommended since safety data beyond 6 months are not available.

Drug Interactions: No pharmacokinetic-based drug-drug interaction studies have been conducted. Nafarelin acetat is a peptide primarily degraded by peptidase and not by cytochrome P-450 enzymes, and is only about 80% bound t plasma proteins at 4°C; therefore drug interactions would not be expected to occur.

Drug/Laboratory Test Interactions: SYNAREL in therapeutic doses suppresses the pituitary-gonadal system. No mal function is usually restored 4–8 weeks after treatment is discontinued. Therefore, diagnostic tests of pituitar gonadotropic and gonadal functions during treatment and up to 4–8 weeks after discontinuation of SYNAREL may b misleading.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Carcinogenicity studies were conducted in rats an mice at intramuscular doses up to 110 times and 560 times the maximum recommended human intranasal dos respectively. These multiples of the human dose are based on the relative bioavailability of the drug by the two routes o administration. As with other GnRH agonists, nafarelin acetate given to laboratory rodents at high doses for prolonge periods induced hyperplasia and/or neoplasia of endocrine organs. At 24 months, there was an increase in the incidence of pituitary tumors (adenoma/carcinoma) in high-dose female rats and a dose-related increase in male rats. There was an increase in pancreatic islet cell adenomas in both sexes, and in benign testicular and ovarian tumors in the treatec groups. There was a dose-related increase in benign adrenal medullary tumors in treated female rats. In mice, there was a dose-related increase in Harderian gland tumors in males and an increase in pituitary adenomas in high-dose females No metastases of these tumors were observed. It is known that tumorigenicity in rodents is particularly sensitive tc hormonal stimulation.

Mutagenicity studies using bacterial, yeast, and mammalian systems provided no evidence of mutagenic potentia

Reproduction studies in male and female rats have shown full reversibility of fertility suppression when treatment was discontinued after continuous administration for up to 6 months.

Pregnancy, Teratogenic Effects: *Pregnancy Category X.* Intramuscular SYNAREL was administered to rats throughout gestation at about 0.5, 2, and 7 times the maximum recommended human intranasal dose based on the relative bioavailability by the two routes of administration. An increase in major fetal abnormalities was seen in 4/80 fetuses at the highest dose. A similar study at the same doses in rats and studies in mice and rabbits at doses up to 600 μg/kg/day and 0.18 μg/kg/day, respectively, failed to demonstrate an increase in fetal abnormalities after administration throughout gestation. In rats and rabbits, there was a dose-related increase in fetal mortality and a decrease in fetal weight with the highest dose.

Nursing Mothers: It is not known whether SYNAREL is excreted in human milk. Because many drugs are excreted in human milk, and because the effects of SYNAREL on lactation and/or the breastfed child have not been determined SYNAREL should not be used by nursing mothers.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: The most frequently reported adverse reactions were those related to hypoestrogenism. In controlled studies comparing SYNAREL (400 μg/day) and danazol (600 or 800 mg/day), the following adverse reac tions were most frequently reported and thought to be drug-related.

Hypoestrogenic: hot flashes (SYNAREL 90%, danazol 69%), decreased libido (22%, 7%), vaginal dryness (19% 7%), headaches (19%, 21%), emotional lability (15%, 18%), insomnia (8%, 4%); **Androgenic:** acne (13%, 20%), myalgia (10%, 23%), reduced breast size (10%, 16%), edema (8%, 23%), seborrhea (8%, 17%), weight gain (8%, 28%), hirsutism (2%, 6%), increased libido (1%, 6%); **Local:** nasal irritation (10%, 3%); **Miscellaneous:** depression (2%, 5%), weight loss (1%, 3%).

Less than 1% of patients experienced paresthesia, palpitations, chloasma, maculopapular rash, eye pain, urticaria, asthenia, lactation, breast engorgement, and arthralgia. In clinical trials, immediate hypersensitivity thought to be pos sibly or probably related to nafarelin occurred in 3 (0.2%) of 1509 healthy subjects or patients.

Changes in Bone Density: After 6 months' treatment vertebral trabecular bone density and total vertebral bone mass, measured by quantitative computed tomography (QCT), decreased by an average of 8.7% and 4.3%, respectively, com pared to pretreatment levels. There was partial recovery of bone density post-treatment; the average trabecular bone density and total bone mass were 4.9% and 3.3% less than pretreatment levels, respectively. Total vertebral bone mass, measured by dual photon absorptiometry (DPA), decreased by a mean of 5.9% at end of treatment. Mean total vertebral mass, re-examined by DPA 6 months post-treatment, was 1.4% below pretreatment levels. There was little, if any, decrease in the mineral content in compact bone of the distal radius and second metacarpal. Use for longer than the recommended 6 months or in presence of other known risk factors for decreased bone mineral content may cause addi tional bone loss.

Changes in Laboratory Values: *Plasma enzymes.* During clinical trials SGOT and SGPT levels were more than twice the upper limit of normal in only one patient each. There was no other evidence of abnormal liver function and levels returned to normal after treatment was stopped.

Lipids. At enrollment and at end of treatment, 9% of patients on SYNAREL 400 μg/day and 2% on danazol had total cholesterol values above 250 mg/dL.

Of those with pretreatment cholesterol values below 250 mg/dL, 6% on SYNAREL and 18% on danazol had post treatment values above 250 mg/dL.

Mean (±SEM) pretreatment values for total cholesterol from all patients were 191.8 (4.3) mg/dL in the SYNAREL group and 193.1 (4.6) mg/dL in the danazol group. At the end of treatment, mean values from all patients were 204.5 (4.8) mg/dL in the SYNAREL group and 207.7 (5.1) mg/dL in the danazol group. These increases from pretreatment values were significant ($p < 0.05$) in both groups.

Triglycerides were increased above the upper limit of 150 mg/dL in 12% of the patients on SYNAREL and in 7% of the patients on danazol.

At the end of treatment, no patients on SYNAREL had abnormally low HDL cholesterol fractions (< 30 mg/dL) com pared with 43% of patients on danazol. No patients on SYNAREL had abnormally high LDL cholesterol fractions (> 190 mg/dL) compared with 15% of those on danazol. There was no increase in the LDL/HDL ratio in patients on SYNAREL, but approximately a 2-fold increase in the LDL/HDL ratio in patients on danazol.

Other changes. In comparative studies, the following changes were seen in approximately 10% to 15% of patients. SYNAREL was associated with elevations of plasma phosphorous and eosinophil counts, and decreases in serum calcium and WBC counts. Danazol therapy was associated with an increase of hematocrit and WBC.

OVERDOSAGE: At present there is no clinical evidence of adverse effects following overdosage of GnRH analogs.

Immunohistochemical localization of prostaglandin H synthase in the female reproductive tract and endometriosis

Bradley J. Van Voorhis, MD, Phyllis C. Huettner, MD, Martin R. Clark, PhD, and Joseph A. Hill, MD

Boston, Massachusetts, and Chapel Hill, North Carolina

Prostaglandin H synthase, also known as cyclooxygenase, is an essential enzyme in prostaglandin synthesis. Using a monoclonal antibody and immunohistochemical techniques, we studied the localization of this enzyme in the female reproductive tract and in endometriosis. In the uterus, prostaglandin H synthase was primarily localized to endometrial epithelium, with surface epithelium containing more immunoreactive prostaglandin H synthase than glandular epithelium. Fallopian tube secretory epithelial cells also contained prostaglandin H synthase while ciliated epithelial cells did not. Cervical epithelium and myometrial cells did not contain prostaglandin H synthase. A higher percentage of glands in endometriosis and adenomyosis, as compared with eutopic endometrium, contained prostaglandin H synthase suggesting that these tissues are also capable of prostaglandin synthesis. These findings may have important physiologic significance in the mechanisms of embryo implantation, in menstruation, and in the pathophysiologic features of endometriosis. (AM J OBSTET GYNECOL 1990;163:57-62.)

Key words: Endometrium, endometriosis, prostaglandins, prostaglandin H synthase, cyclooxygenase

Prostaglandins have been implicated in numerous aspects of reproductive function and the human reproductive tract is an important site of prostaglandin synthesis. Tissue culture studies have demonstrated prostaglandin production by the fallopian tube,[1] myometrium,[2] and endometrium.[3] In addition, ectopic endometrium has been shown to produce prostaglandins that may contribute to the pathophysiology of endometriosis and adenomyosis.[4, 5] Although many studies have examined prostaglandin production by these tissues, few studies have attempted to localize the cells responsible for prostaglandin production. The purpose of our study was to identify the site of prostaglandin synthesis in the human fallopian tubes, uterus, and endometriosis by immunohistochemical localization of prostaglandin H (PGH) synthase, an essential enzyme in prostaglandin synthesis.

Material and methods

Patients. Tissue sections were cut from formalin-fixed paraffin-embedded specimens obtained from premenopausal women (age range 30 to 49) undergoing laparotomy for benign conditions. Uterine specimens ($n = 45$) were obtained from women at different stages of the menstrual cycle (9 menstrual phase, 11 proliferative phase, and 25 secretory phase). Tissue sections for study were obtained from the uterine fundus. Designation of menstrual cycle day was made by histologic dating. Adenomyosis was identified in nine uterine specimens, and in 18 women pelvic endometriotic tissue also was available for study. In five women tissue sections were obtained from the ampullary, isthmic, and infundibular portions of the fallopian tube and from the cervix for immunohistochemical evaluation.

Antibody. Monoclonal antibodies to PGH synthase were prepared as previously described.[6] Briefly, PGH synthase was purified from sheep seminal vesicle microsomes by chromatography on diethylaminoethyl cellulose and lentil lectin Sepharose. BALB/c mice were immunized with 50 μg of PGH synthase and screened for antibody production by immunoprecipitation and enzyme immunoassay. Splenic lymphocytes were fused to SP2/O myeloma cells. Hybridoma medium containing PGH synthase–specific antibodies, as determined by enzyme-linked immunosorbent assay and immunoblots, was used for immunohistochemistry.

Immunohistochemistry. Surgical specimens were

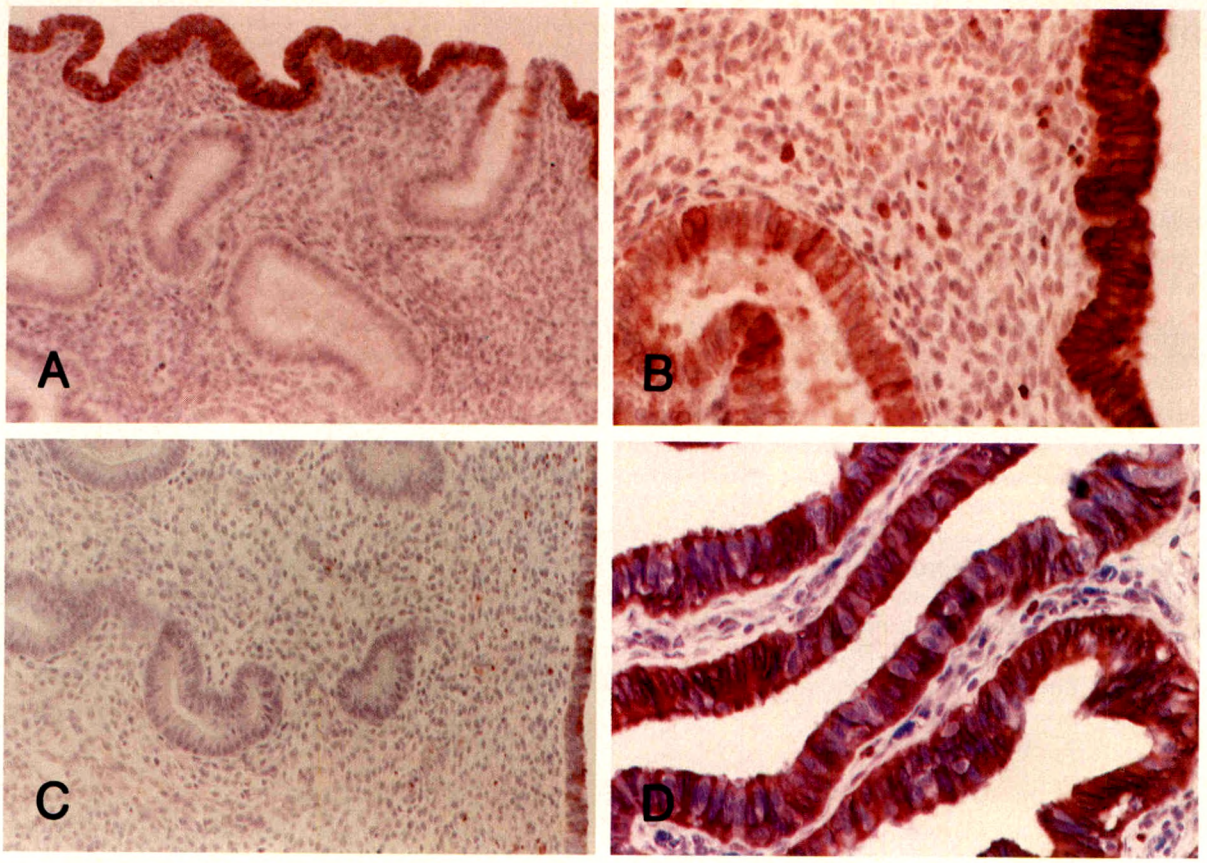

Fig. 1. A, Secretory endometrium (day 20) with positive surface epithelium. **B,** Secretory endometrium (day 19) with positive surface epithelium, glandular epithelium, and occasional stromal cells. **C,** Late proliferative endometrium with 1+ positive surface epithelium. **D,** Tubal epithelium with positive secretory cells and negative ciliated cells.

routinely fixed in neutral-buffered 10% formalin, processed, and embedded in paraffin. Sections were cut (6 μm) and mounted on slides. Dried slides were baked at 56° C for 2 hours, deparaffinized in xylene, rehydrated through an ethanol series, and treated with 3% hydrogen peroxide in methanol to block endogenous peroxidase activity. The slides were then washed in phosphate-buffered saline solution. Immunohistochemistry was performed with a streptavidin-biotin-peroxidase system (Histostain SP-kit, Zymed Laboratories, South San Francisco). Briefly, tissue sections were treated with nonimmune rabbit serum for 10 minutes to saturate nonspecific binding sites. Excess serum was blotted from the slides and then incubated with PGH synthase antibody at a 1:40 dilution in phosphate-buffered saline solution for 30 minutes at 37° C. In several specimens sequential tissue sections were stained with Dako LC (Dako Corp., Santa Barbara) substituted for anti–PGH synthase as the primary antibody. Biotinylated secondary antibody was then added (10 minutes) followed by the streptavidin-peroxidase conjugate (5 minutes) and the substrate-chromogen (aminoethylcarbazole). Finally, the tissues were counterstained with hematoxylin and mounted with an aqueous mounting solution (GVA-mount, Zymed). After each step the sections were washed with phosphate-buffered saline solution. Slides were independently interpreted by two observers. Staining was graded as 2+ for strongly reactive staining, 1+ for weakly reactive but still specific staining, and 0 for no reactivity.

The immunohistochemical specificity was determined by substitution of the primary antibody with phosphate-buffered saline solution, normal mouse serum, and nonspecific mouse immunoglobulin M (Calbiochem, La Jolla) at 2.5 μg/ml, the concentration of our PGH synthase antibody at a 1:40 dilution. In addition, the primary antibody was preabsorbed with purified PGH synthase (Oxford Biomedical Research, Oxford, Mich.) using a dilution of 10 μl of antibody and 90 μl (45 μg) of antigen before processing for immunohistochemistry.

To eliminate possible confounding effects of for-

malin tissue fixation, five endometrial biopsy specimens from women in the secretory phase were immediately frozen in O.C.T. freezing compound (Miles Scientific, Naperville, Ill.). Slides of 6 μm cryostat sections were fixed in acetone for 10 minutes before we proceeded with immunohistochemical staining.

Western blot analysis. Endometrial specimens were removed and frozen at −70° C. Solubilization of PGH synthase was performed as previously reported[6] and Western blot analysis was performed. Polyacrylamide gel electrophoresis in sodium dodecyl sulfate was run on an 8% to 25% gradient gel in a PhastGel system (Pharmacia, Pleasant Hill, Calif.). PGH synthase standard (1.3 ng, Calbiochem, San Diego) was run in an adjacent lane. An aliquot of 4.4 μg of protein from endometrium was analyzed. Proteins were transferred to nitrocellulose with a Polyblot transfer system (American Bionetics, Hayward, Calif.). The blot was blocked with 2% nonfat dry milk dissolved in phosphate-buffered saline solution for 24 hours at 4° C, followed by an avidin-biotin blocking step. The blot was then incubated in 2.5 μg/ml anti–PGH synthase for 2 hours at room temperature and for 16 hours at 4° C. Bound primary antibody was detected with an avidin-biotin–alkaline phosphatase kit from Vector Labs (Burlingame, Calif.).

Results

In the uterus endometrial surface epithelium demonstrated the most intense immunoperoxidase staining for PGH synthase in nearly all specimens examined. In proliferative phase endometrial samples, the surface epithelium was strongly reactive in 5 of 11 specimens and weakly reactive in the remaining 6. The surface epithelium of secretory endometrium was strongly reactive in 23 of 25 specimens with the remaining specimens demonstrating weak reactivity. When surface epithelium was present in menstrual phase specimens, staining for PGH synthase was always strongly reactive. An abrupt transition in staining for PGH synthase was noted between surface epithelium and glandular epithelium at the gland openings. While surface epithelium was nearly always strongly reactive, most glandular epithelium demonstrated either weak reactivity

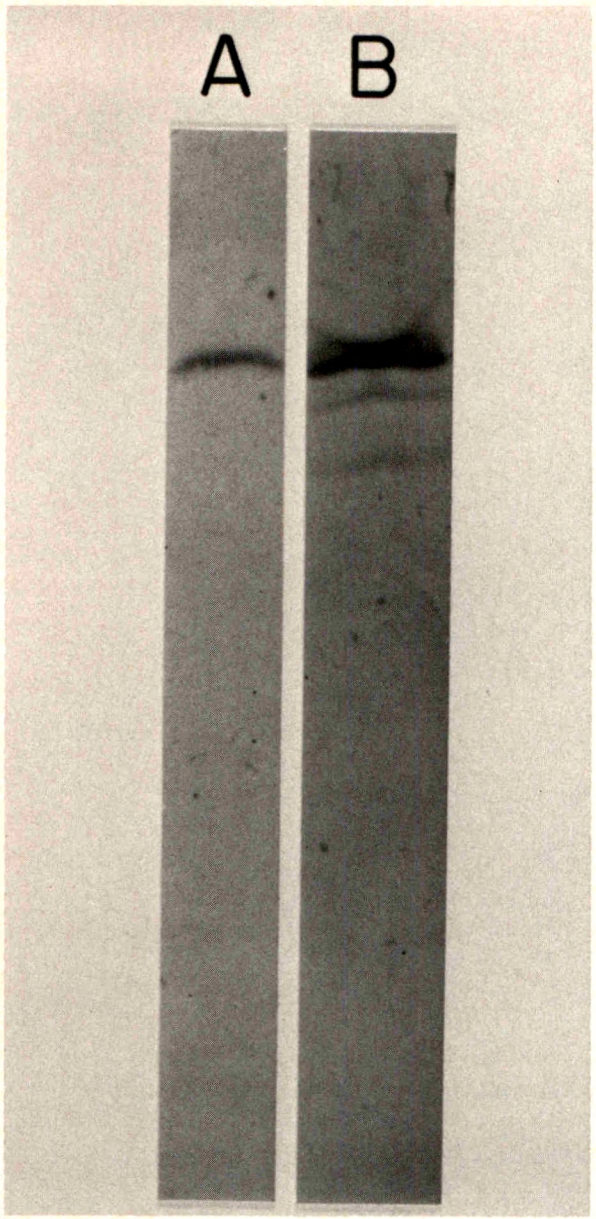

Fig. 2. Western immunoblot of 4.4 μg of protein extracted from human endometrium *(lane A)* and 1.3 μg of PGH synthase standard *(lane B)* electrophoresed on a polyacrylamide gel.

(20% of glands) or no reactivity (75% of glands). Only 5% of glands were strongly reactive. This staining pattern of glandular epithelium was consistent in menstrual, proliferative, and secretory endometrium. No distinct pattern could be discerned when glands of the stratum basalis were compared with glands of the stratum functionalis (Fig. 1, *A*, *B*, and *C*).

Scattered endometrial stromal cells were strongly reactive with an average density of three positive cells per high-power field. However, a large majority of stromal cells were negative. No differences in positively stained cell density was observed when sections from different phases of the cycle were compared (Fig. 1, *B*).

Myometrial cells did not stain for PGH synthase, but scattered positive cells were seen in the interstitial connective tissue at an average density of 15 positive cells per high-power field (×400). These cells were present in all uterine specimens, and no differences were noted at different phases of the menstrual cycle. The positive cells were of white blood cell origin on the basis of morphologic features and positive staining with the white blood cell antibody Dako LC.

In the fallopian tube, mucosal secretory cells were intensely (2+) reactive for PGH synthase. Ciliated mucosal cells and cells in the connective tissue of the lamina propria were negative. The smooth muscle of the fallopian tube was weakly (1+) reactive. No difference in this pattern was seen when tissue from different areas of the fallopian tube were compared (Fig. 1, *D*).

In the cervix the columnar epithelium lining the endocervical canal and the epithelium of cervical glands were negative for PGH synthase. The squamous epithelium of the cervix also was negative. Rare scattered positive cells were present in the connective tissue of the cervix. Vascular smooth muscle present in uterine specimens was only weakly reactive for PGH synthase while vascular endothelium was negative (Fig. 1, *E*).

A higher percentage of ectopic endometrial glands demonstrated intense reactivity as compared with normal endometrial glands. In 9 specimens of adenomyosis, a median of 40% of glands were intensely stained (range 5% to 75%). In 18 specimens of endometriosis, a median of 50% of glands were intensely stained (range 0% to 100%). In 9 cases of ovarian endometriomas, the epithelial cyst lining was always strongly positive. Rare stromal cells around the ectopic endometrial glands also were strongly positive. No distinct patterns could be discerned when pathologic specimens from different phases of the menstrual cycle were compared (Fig. 1, *F* and *G*).

When multiple sections of the same tissue specimen were examined, identical staining patterns were observed in each section. No staining was observed in control sections when the PGH synthase antibody was replaced with phosphate-buffered saline solution, normal mouse serum, or nonspecific mouse IgM. Preabsorbing the antibody with purified PGH synthase also resulted in no staining of tissue (Fig. 1, *H*). Fresh-frozen endometrial tissue sections demonstrated identical staining patterns as seen in formalin-fixed tissues.

On gel electrophoresis and Western blotting, the PGH synthase antibody reacted with purified sheep PGH synthase. Analysis of protein extracted from human endometrium revealed cross-reactivity with an antigen that comigrated with the sheep PGH synthase.

The approximate relative molecular mass of the proteins was 72 kd (Fig. 2).

Comment

Prostaglandins are involved in many physiologic processes in the female reproductive tract. Investigators have proposed a role for prostaglandins in tubal motility[1] and menstruation.[7] In addition, animal studies have implicated prostaglandins in uterine implantation of the embryo and the decidual cell reaction.[8, 9] Many investigators have studied the in vivo and in vitro production of prostaglandins by human reproductive tract tissues, but cellular localization of prostaglandin synthesis within these tissues has not been systematically performed.

PGH synthase, also known as cyclooxygenase, is an essential enzyme in prostaglandin synthesis as it is the first enzyme of the pathway in which arachidonic acid is converted to prostanoids such as prostacyclin, thromboxane A_2, and prostaglandins E_2 and $F_{2\alpha}$. The purpose of this study was to identify the cells containing PGH synthase in the human female reproductive tract and in endometriotic tissue by immunohistochemical techniques. The monoclonal antibody we used, although produced against sheep PGH synthase, is not species-specific but rather cross reacts with PGH synthase from many other species,[6] including humans.[10] This was confirmed by our Western blot analysis, which demonstrated antibody reactivity with a human antigen that comigrated with sheep PGH synthase standard on gel electrophoresis. The approximate relative molecular mass of 72 kd correlates well with previously published studies characterizing the enzyme.[11]

In uterine specimens, the most intense staining for PGH synthase occurred in the surface epithelium of the endometrium. An obvious difference in staining between the surface and glandular epithelium could be discerned starting abruptly at the gland neck. In contrast to the uniformly intense staining of surface epithelium, only 5% of glands were intensely stained and most (75%) were negative for PGH synthase. The possibility that surface epithelium and glandular epithelium have differing cellular characteristics has been previously suggested. Lee and Damjanov,[12] utilizing soybean agglutinin for histochemical identification of terminal *N*-acetylgalactosamine, demonstrated staining of surface but not glandular epithelium. Using electron microscopy, Ferenczy et al [13] detected morphologic differences between these cell types. The presence of immunoreactive PGH synthase in surface epithelium suggests it is capable of prostaglandin synthesis. In animal studies there is increasing evidence that the luminal epithelium may synthesize prostaglandins at the time of implantation. In the mouse, Kennedy[8] has suggested that luminal epithelial cells may respond to embryonic signals by initiating prostaglandin synthesis. The prostaglandins may then diffuse into the underlying stroma to increase vascular permeability. Parr et al.[9] studied immunohistochemical localization of prostaglandin synthase in the rat uterus at implantation and noted staining of both luminal epithelium and adjacent decidualized stromal cells. Further work is needed to determine if surface epithelium prostaglandin synthesis is important in human implantation.

In addition to PGH synthase–positive cells in the endometrial epithelium, occasional positive cells were noted in the uterine stroma and interstitial connective tissue of the myometrium. Myometrial cells and the majority of stromal cells were negative for PGH synthase. The positive cells noted in myometrial connective tissue are leukocytic cells on the basis of morphologic features and positive staining with a monoclonal antibody to leukocytes, Dako LC. Uterine stroma is made up of a heterogeneous population of cells including uterine stromal cells and leukocytes.[14] The precise cell type in the stroma that contained PGH synthase could not be positively identified because of obscuring of morphologic features by peroxidase staining. We propose that these cells may be macrophages, which are known to produce prostaglandins.[15]

Prostaglandin production by the human endometrium increases during the luteal phase.[7] To determine if an increase in immunoreactive PGH synthase could contribute to increased prostaglandin synthesis in the human luteal phase, endometrium from different days of the cycle was examined. We found increased immunostaining of surface epithelium in the luteal phase as compared with the proliferative phase. However, no differences in staining of glands, stromal cells, or myometrium could be demonstrated.

One previous immunohistochemical study of PGH synthase in the human uterus has been performed. Rees et al.[16] noted intensely positive staining of all surface epithelium and most glands in luteal phase specimens. In contrast to our study, they noted no specific staining in any proliferative phase specimens or in the uterine stroma or myometrium. Tissue explant studies support our findings as they have demonstrated prostaglandin production by proliferative phase endometrium and separated stromal cells, suggesting that PGH synthase is present in these tissues.[5] Difference between these two studies might be accounted for by use of different antibodies and by their use of unfixed tissue.

We observed immunoreactive PGH synthase in the tubal mucosal secretory cells, while ciliated cells of the tubal mucosa were negative. Interestingly, the smooth muscle of the fallopian tube contained immunoreactive PGH synthase, in contrast to the myometrium, which was negative. Our findings of immunoreactive PGH synthase support previous studies that have demon-

strated prostaglandin production by the human fallopian tube.[14]

In the cervix no staining of endocervical lining, glandular epithelium, or squamous epithelium was observed. Obvious differences in immunoreactive prostaglandin synthase content were noted when epithelium of the cervix was compared with uterine surface epithelium. These results indicate that epithelium derived from the müllerian duct differs in PGH synthase content depending on location and differentiation.

Prostaglandin production by endometriotic tissue has been demonstrated in vitro. Vernon et al.[4] demonstrated differing capacities of prostaglandin production by endometriotic implants on the basis of gross morphologic features of the lesion. They speculated that lesions producing large amounts of prostaglandin were "early" implants with increased numbers of functional glands present. Our findings also would suggest that glandular epithelium in endometriosis may be important in prostaglandin synthesis as prostaglandin synthase was primarily localized in this epithelium. Forty percent of endometriotic glands and the epithelium of all ovarian endometriomas were intensely positive for PGH synthase. Glandular epithelium in adenomyosis also stained intensely for PGH synthase. Ectopically located glands in both adenomyosis and endometriosis were more often intensely positive for PGH synthase than eutopic endometrial glands (50% vs 5%). This further supports the concept that ectopic and eutopic endometrium are dissimilar.

Our findings indicate that the epithelium of the female reproductive tract contains immunoreactive PGH synthase. Within the epithelial layer, levels of PGH synthase vary depending on location and cellular differentiation. Surface epithelium of the endometrium stains intensely for PGH synthase and has more immunoreactive PGH synthase than glandular epithelium. Ectopic glandular epithelium in endometriosis and adenomyosis also contains PGH synthase. Although staining of PGH synthase cannot be equated with levels of prostaglandins produced, our findings suggest that endometrial surface epithelium and glandular epithelium in endometriosis and adenomyosis are capable of prostaglandin synthesis.

We thank Julie Kelleher for her help in preparing the manuscript.

A case of Rh isoimmunization: Should threatened first-trimester abortion be an indication for Rh immune globulin prophylaxis?

Vanessa D. Dayton, MD,[a] Deborah S. Anderson, BS,[a] John T. Crosson, MD,[a, c] and Stephen H. Cruikshank, MD[b, c]

Minneapolis, Minnesota

Despite the recommended 28 weeks' gestation antenatal, postnatal, and postabortion prophylaxis with Rh immune globulin, residual Rh immunization still occurs in Rh-negative women. We describe a patient whose history suggests development of an anti-D antibody after first-trimester bleeding. To our knowledge, this is the first such case reported in the English literature. (AM J OBSTET GYNECOL 1990;163:63-4.)

Key words: Rh isoimmunization; bleeding, first trimester; Rh immune globulin, indications

Antepartum bleeding without loss of the conceptus carries some risk of transplacental hemorrhage. However, threatened abortion in the first trimester of pregnancy is not typically included in published lists of indications for Rh immune globulin administration.

We report a case of a 35-year-old $Rh_o(D)$-negative woman who was seen between 8 and 9 weeks' gestation with vaginal bleeding and a viable intrauterine pregnancy verified by ultrasonography. Because the pregnancy was not terminated, Rh immune globulin was not administered. The patient received Rh immune globulin at 15 weeks' (after amniocentesis) and 29 weeks' gestation.

Since vaginal bleeding in the first trimester of pregnancy occurs commonly, Rh immune globulin administration to all $Rh_o(D)$-negative women with threatened abortion could be costly. However, many believe the benefits of avoiding any possible cases of Rh isoimmunization outweigh the costs.[1] The present case offers support for administration of Rh immune globulin to $Rh_o(D)$-negative women with significant vaginal bleeding in the first trimester of pregnancy.

Case report

A 35-year-old woman, gravida 6, para 1-0-4-1, was seen in an emergency department in the eastern United States on Sept. 6, 1988, complaining of pelvic cramping and passage of blood clots through the vagina. Her last normal menstrual period was on June 9, 1988.

Her past obstetric history was significant for four elective abortions and one live birth of an $Rh_o(D)$-negative child. The previous birth was of a child fathered by her first husband whose blood type was O, $Rh_o(D)$ negative. The current pregnancy was with a second husband. Administration of Rh immune globulin was documented for the first and most recent abortions. According to the patient, it was also given after the other two abortions. The antibody screen was negative at the time of first abortion and first delivery. Other records are no longer available. The patient denied any history of blood product transfusion other than Rh immune globulin.

At the time of the emergency department visit in 1988, a speculum examination revealed a cyanotic gravid cervix with a closed os. A small amount of red-brown discharge was observed in the vaginal vault.

An abdominal ultrasonogram revealed a viable fetus estimated to be 8.5 weeks' gestational age. Neither maternal blood typing nor the Kleihauer-Betke test was performed.

The patient was discharged from the emergency department and advised to follow up with her local obstetrician. Rh immune globulin was not given.

On Sept. 20, 1988, the patient was seen for the first time in a local obstetric clinic, and routine prenatal laboratory studies were performed. The patient's blood type was A, $Rh_o(D)$ negative, and an antibody screen was negative with low-ionic-strength saline solution and two-stage papain enzyme technique.

On Oct. 20, 1988, amniocentesis with ultrasonographic guidance was performed at another facility for genetic counseling. Ultrasonography revealed a 15-week, anatomically normal fetus. An antibody screen

6/1/19491

performed with low-ionic-strength saline solution only was negative, and therefore 300 μg of Rh immune globulin was given intramuscularly.

On Feb. 1, 1989 (approximately 29 weeks' gestation), the patient transferred her care to our institution. A routine antibody screen was positive, with anti-D specificity in low-ionic-strength saline solution with indirect antiglobulin testing and with two-stage papain techniques. Initial communications between our transfusion service and prior care givers suggested that these findings could be consistent with passive antibody, and 300 μg of Rh immune globulin was given intramuscularly for routine antenatal prophylaxis.

On April 6, 1989 (approximately 39 weeks' gestation), the patient was delivered of a live, 3330 gm female infant. The infant's cord blood type was O, $Rh_o(D)$ positive, and the direct antiglobulin test was strongly positive on cord blood cells. Rh immune globulin was released on the basis of the belief that the infant's positive direct antiglobulin test was secondary to antenatal maternal Rh immune globulin. At a subsequent transfusion service case review, the discrepancy of the strong positive cord blood direct antiglobulin test was noted and maternal anti-D quantitation was performed on an immediate postpartum serum specimen. The maternal IgG anti-D titer was 1/4096. A repeat screen at 6 months post partum continued to show anti-D with a titer of 1/1024. The infant's bilirubin level was 2.6 μ/dl at birth and rose to a peak level of 9.3 μg/dl on the seventh day. The infant's hemoglobin was 10.5 gm/dl on the seventh day and dropped to a nadir of 8.5 gm/dl on the fourteenth day.

Comment

According to *Williams' Obstetrics*, eighteenth edition (Appleton & Lange), one of every four or five women has vaginal spotting or heavier bleeding during the early months of pregnancy. Of those, only half subsequently have complete abortion. There does not seem to be a clear consensus in the literature on the use of Rh immune globulin for first-trimester bleeding without loss of the conceptus in $Rh_o(D)$-negative women. Some authors include this situation in their recommendations for Rh immune globulin use.[1] Some do not discuss threatened abortion in reviews of Rh immune globulin prophylaxis,[2] while others recommend making a decision on the basis of determinations of fetal cells in the maternal circulation.[3] It has been established that a very small volume of $Rh_o(D)$-positive blood can sensitize an $Rh_o(D)$-negative individual[1] and, for this reason, use of Rh immune globulin has been advised for routine prophylaxis after chorionic villus sampling as early as 8.5 weeks.[3]

Our case illustrates three important points. First, it is possible to become $Rh_o(D)$ sensitized after a minor first-trimester hemorrhage with resultant risk of hemolysis in the infant. Had this case represented an amnestic response from a previous exposure, anti-D should have been apparent with enzyme testing at the time of the first screening test in light of the bleeding episode 2 weeks previously. The patient received adequate prophylaxis with Rh immune globulin for the amniocentesis, and no other obvious events would explain the sensitization that occurred during the pregnancy. Second, although antenatal maternal Rh immune globulin is probably the most common explanation for a neonatal positive direct antiglobulin test with anti-D specificity, a strongly positive newborn direct antiglobulin test should be carefully reviewed to avoid missing a case of maternal sensitization. Third, although obstetricians and gynecologists may be aware that Rh immune globulin should be given when there is doubt, emergency department personnel may not. On the basis of the example of this case, our institution will be revising its recommendations for the use of Rh immune globulin to include first-trimester bleeding in $Rh_o(D)$-negative women, regardless of whether they do undergo abortion. Our revised guidelines will be given to our Emergency Medicine staff as well as to physicians in obstetrics and gynecology.

Antisperm antibodies in women undergoing intrauterine insemination

Jeffrey M. Goldberg, MD, Paul L. Haering, Chad I. Friedman, MD, William G. Dodds, MD, and Moon H. Kim, MD

Columbus, Ohio

Intrauterine insemination is widely used for the treatment of infertility as a result of cervical or male factors or empirically before in vitro fertilization or gamete intrafallopian transfer. This study was designed to confirm or refute the theoretical concern that intrauterine insemination may induce antisperm antibodies in such women. Serum and cervical mucus were obtained at the first, fourth, and sixth intrauterine inseminations. The serum was screened by the Immunobead test for IgG and IgA. If screening results were positive (>10% binding), antisperm antibodies were titered by the microimmobilization and microagglutination tests. The Immunobead test was performed on the cervical mucus after liquefication with bromelin. Ninety-three patients were followed up prospectively. Of these, 40 completed six intrauterine insemination cycles and the remaining 53 completed four cycles. Low transient antisperm antibody levels were detected in 10.8% of the patients and would not be expected to affect the prognosis for fertility. It is concluded that intrauterine insemination does not induce significant antisperm antibody production in women. (AM J OBSTET GYNECOL 1990;163:65-8.)

Key words: Antisperm antibodies, intrauterine insemination, cervical mucus, immune factor infertility

Intrauterine insemination is an accepted therapeutic modality for the treatment of infertility caused by abnormalities in the cervical mucus, semen analysis, or sperm-mucus interactions. It is also used as empiric treatment for infertility as a result of other causes, including unexplained infertility, before more expensive and invasive in vitro fertilization and gamete intrafallopian transfer procedures are considered.[1] Several studies have suggested that intrauterine insemination during superovulation cycles further improves pregnancy rates.[2-4] There is a hypothetical concern that intrauterine insemination may sensitize the patient to produce antisperm antibodies.[1, 5] This may be attributed to the greater number of sperm (antigenic load) entering the upper genital tract and peritoneal cavity and the inoculation schedule. In addition, the sperm-washing procedure removes seminal immune suppressor factors.[6-9] Previous studies concluded that sensitization does not occur to a significant degree with intrauterine insemination; however, the numbers of study patients were small, the number of cycles was not standardized, and no attempt was made to identify antisperm antibodies in the cervical mucus.[10, 11] The goal of this study was to provide a more definitive answer by addressing these factors.

Material and methods

Ninety-three patients undergoing intrauterine insemination therapy for infertility were studied prospectively. The indication for intrauterine insemination was dysmucorrhea (n = 19), male factor (n = 25), poor mucus plus male factor (n = 3), poor result of Huhner test (with good mucus and normal semen analysis, n = 23), and empiric treatment (n = 23). Serum and cervical mucus were obtained at the time of the first, fourth, and sixth intrauterine inseminations (i.e., baseline and after the completion of three and five cycles, respectively). Not unexpectedly, several mucus specimens were insufficient for analysis, especially in the group with dysmucorrhea. Patients who conceived before the fourth cycle were excluded. No patient received more than six intrauterine insemination treatments. All patients received either clomiphene citrate or human menopausal gonadotropins. Human chorionic gonadotropin, 5000 U intramuscularly, was administered when transvaginal ultrasonography revealed one or more follicles with a mean diameter at least 18 mm in the group treated with clomiphene citrate or 16 mm in the group receiving human menopausal gonadotropins. Intrauterine insemination was timed 28 to 36 hours later.

specimens were obtained from the husband by masturbation into a sterile jar. No donor inseminations were included. After liquefaction a small aliquot was removed for semen analysis with a Makler chamber. The specimen was washed twice by centrifugation at 800 *g* for 5 minutes in Ham's F-10 media (Gibco, Grand Island, N.Y.). The final pellet was resuspended in 0.3 ml of media, without swim-up, and the sperm concentration and motility were recorded. The total volume inseminated was 0.4 to 0.5 ml. The exocervix was wiped with a cotton ball and the cervical mucus was aspirated into a tuberculin syringe. Intrauterine insemination was accomplished with a Unimar intrauterine catheter (Unimar, Wilton, Conn.) and blood was obtained by venipuncture. The serum and cervical mucus specimens were frozen for later antisperm antibody assay at the completion of the study. Only one insemination was performed each cycle. Three donors with proved fertility and negative direct Immunobead testing provided the sperm for the assays. Direct Immunobead testing was performed selectively on the patients' husbands when agglutination was noted on semen analysis, the Huhner test result was abnormal with good cervical mucus (i.e., immotile or shaking sperm), or with long-standing unexplained infertility.

Cervical mucus liquefaction.[12-14] The cervical mucus was liquefied by addition of an equal volume of Tyrode's solution (Sigma, St. Louis, Mo.) with 0.3% bovine serum albumin (Sigma) containing 2 mg/ml of bromelin (Sigma). The mixture was aspirated repeatedly through a 22-gauge needle until it was completely liquefied (up to 60 minutes at room temperature). For a few specimens, additional bromelin was required to achieve full liquefaction. The mixture was then centrifuged at 800 *g* for 10 minutes. The supernatant was removed and heat-inactivated at 56° C for 30 minutes.

Indirect Immunobead test.[15, 16] The liquefied donor semen specimen was adjusted with Tyrode's solution to a concentration of 6 to 9 × 10^6 motile sperm per milliliter and 100 μl incubated with 200 μl heat-inactivated patient's sera for 1 hour at 37° C. The sperm were washed three times in 5 ml of Tyrode's solution with 0.3% bovine serum albumin at 800 *g* for 5 minutes at 37° C. The final sperm pellet was resuspended in 100 μl Tyrode's solution with 5% bovine serum albumin. The Immunobeads were prepared by washing 200 μl of 5 mg/ml of rabbit antihuman IgG–and IgA–bound latex beads (Bio-Rad, Richmond, Calif.), each in 10 ml of Tyrode's solution with 0.3% bovine serum albumin, as was done for the sperm. The bead pellets were resuspended in 200 μl of Tyrode's solution with 5% bovine serum albumin. Finally, 5 μl of each Immunobead solution was incubated separately with 5 μl of serum-reacted sperm on a glass slide for 5 minutes, then examined by phase-contrast microscopy (×400). At least 10% of the motile sperm must be bound by

beads for the result to be considered positive. The locations of bead attachment were also recorded. All specimens were run with known positive and negative control sera. The Immunobead test on the liquefied cervical mucus was identical. The entire volume of cervical mucus supernatant, up to 200 μl, was used for the assay.

Because no positive cervical mucus control was available, a positive serum control treated in an identical fashion as the mucus served as the positive control. In addition, an untreated aliquot of the same positive control serum was run as a further control. Bromelin treatment of the positive control serum did not affect the results of Immunobead testing with any of the assays used in this study.

Modified microagglutination test.[17] Heat-inactivated patients' and positive control sera were serially diluted with Tyrode's solution from 1:4 to 1:128, and 5 μl of each dilution was added to the wells of a Terasaki tissue culture tray containing 5 μl of paraffin oil per well. Donor semen was adjusted with Tyrode's solution to a sperm concentration of 25 to 30 × 10^6 ml, 1 μl of which was added to each well. The tray was incubated at room temperature for 2 to 3 hours and was then examined with an inverted phase-contrast microscope. The highest titer exhibiting sperm agglutination was reported. Tyrode's solution plus sperm served as a negative control.

Modified microimmobilization test.[18] Patients' and positive control sera were serially diluted and added to a Terasaki tray with paraffin oil as in the modified microagglutination test. To each well 1 μl guinea pig complement (Gibco) was added. Tyrode's solution plus complement, and patients' sera with heat-inactivated complement, were the negative controls. Donor semen was adjusted to 40 to 60 × 10^6 sperm per milliliter and 1 μl added to each well. The tray was incubated for 1 hour at 37° C, then examined on an inverted phase-contrst microscope. The highest dilution with >50% immobilization was reported.

Results

Forty patients completed six intrauterine insemination cycles and an additional 53 completed four cycles. The 10 patients (10.8%) who tested positive for antisperm antibodies are summarized in Table I. No patient had a positive serum microimmobilization test or cervical mucus positive for IgG on Immunobead testing. Of the 10 patients with positive serum Immunobead testing, seven had IgG, two had IgA, and one had both. One patient had IgA on the cervical mucus Immunobead test. The serum was also positive for IgG.

The mean and standard deviation of the concentration of total sperm inseminated (millions per milliliter) was 126.5 ± 80.2 for the unsensitized group and 124.5 ± 57.3 for the sensitized group. The concentration of motile sperm inseminated was 61.2 ± 50.3 and 76.9 ± 75.4 for the two groups, respectively. Statistical analysis with analysis of variance revealed no significant difference between sensitized and unsensitized women for postwash total concentration ($p = 0.96$) and for postwash motile concentration ($p = 0.38$). Fifty-five (59.1%) of the husbands were tested for antisperm antibodies. Nine of 51 (17.6%) of the husbands of unsensitized women tested positive, compared with one of four (25%) of the husbands of sensitized patients. The percentage of husbands with positive antisperm antibodies was not significantly different between the two groups of women (Fisher's exact test, $p = 0.56$).

Comment

Kremer[19] reported that intrauterine insemination led to an increase in antisperm antibody titers in five of five women previously sensitized; however, none of the 20 unsensitized women developed antisperm antibodies after six intrauterine insemination cycles. Overstreet et al.[20] retested the initial sera on 13 of 14 patients that had become sensitized (30% to 50% binding on Immunobead testing) after two to 13 cycles. Five of these were positive (20% to 40% binding) on retesting. They concluded that low levels of antisperm antibodies may be significantly increased as a result of intrauterine insemination. Moretti et al.[10] tested sera of 41 patients before and after one to 15 intrauterine insemination cycles with agglutination and immobilization assays and the Immunobead testing. One patient had a low agglutination titer initially, which remained unchanged after nine intrauterine insemination cycles. Another patient had a positive agglutination and Immunobead test for IgG and IgM after a single insemination. A third patient converted to a positive immobilization test after nine cycles. Horvath et al.[11] performed the Immunobead test on sera at baseline and serially up to six intrauterine insemination cycles. All patients were treated with human menopausal gonadotropins or clomiphene citrate and human menopausal gonadotropins. Twenty-eight patients received intrauterine insemination and 25 served as controls. Only 10 patients in the intrauterine insemination group completed six cycles. They demonstrated no significant difference in antisperm antibody levels between the two groups.

Our data indicate that there is no significant induction of antisperm antibody production in unsensitized women, or increase in low antisperm antibody titers present at baseline. Because no patients in our series had high antisperm antibody titers initially, we cannot address what effect intrauterine insemination would have in this situation. Higher total and motile sperm concentrations or the presence of antisperm antibodies

on the husbands' sperm did not predispose the development of antisperm antibodies.

The Immunobead test was selected as the screening test because it provides additional information with regard to the antibody class and the regions of the sperm bound by antibody. It is also less subject to nonspecific binding than the agglutination and immobilization assays. We used an arbitrary positive threshold of 10% Immunobead binding to define a positive antibody reaction in hopes of improving sensitivity. It should be noted that all of our patients with a positive Immunobead test result had Immunobead binding below 50%. Horvath et al.[11] noted that there are no data that correlate the percentage of Immunobead binding with subsequent conception rates. Although the clinical implication of our low threshold is unknown, it should be recognized that it was often associated with a serum microagglutination test titer of <1:8, which is rarely correlated with infertility.

In our study only one patient (1.1%) had a positive Immunobead test result on the cervical mucus. This result is lower than that reported previously.[14,15] Earlier studies demonstrated a strong correlation between cervical mucus Immunobead test positivity and positive serum immobilization testing. In our series no patient had a positive serum immobilization test. These discrepancies may be attributed to differences in patient populations. In addition, since antisperm antibodies may enter the cervical mucus by transudation from the vascular system, the low serum levels may have been inadequate to yield a sufficient concentration in the cervical mucus to exceed the sensitivity of the Immunobead test. That our patient had IgA in the cervical mucus and IgG in serum suggests that the IgA was produced locally in the cervix. Degradation of immunoglobulins by the proteolytic enzyme bromelin, which was used to liquefy the cervical mucus, has been discounted by previous investigators.[12-15] To further ensure that the low incidence of cervical mucus antisperm antibodies was not a result of an effect of bromelin, we treated positive control sera in an identical fashion to the cervical mucus and found no alteration in antisperm antibody test results. Currently there is no clinical method to assess the uterine and fallopian tube environments for local antisperm antibody production.[11]

In summary, our data provide further support to reduce the concern that intrauterine insemination may commonly induce significant antisperm antibody production in unsensitized women or increase titers in those with preexisting low levels. Whether intrauterine insemination will further raise high antisperm antibody titers remains open to speculation. More importantly, the broader questions regarding the value of intrauterine insemination and the clinical significance of antisperm antibody are still unresolved.

Expression of P-glycoprotein in epithelial ovarian cancer: Evaluation as a marker of multidrug resistance

Stephen C. Rubin, MD, Connie L. Finstad, PhD, William J. Hoskins, MD, Patricia E. Saigo, MD, Diane M. Provencher, MD, Mark G. Federici, BS, Thomas B. Hakes, MD, Maurie Markman, MD, Bonnie S. Reichman, MD, Kenneth O. Lloyd, PhD, and John L. Lewis, Jr., MD

New York, New York

The multidrug-resistance gene, MDR1, encodes a plasma membrane glycoprotein termed P-glycoprotein that mediates active cellular efflux of certain chemotherapeutic agents. P-Glycoprotein expression was evaluated in 98 frozen tumor specimens from 57 patients with epithelial ovarian cancer by the indirect immunoperoxidase technique with monoclonal antibodies C219 and JSB-1 used for detection. Tumor specimens were further characterized antigenically with a panel of monoclonal antibodies representing a variety of epithelial cell antigens. Included were 57 specimens from 33 previously untreated patients; 11 specimens were also available from eight patients in this group after chemotherapy. An additional 30 specimens were studied from 24 other patients after chemotherapy. In only four of the 57 patients with ovarian cancer (7%) did one or more of the specimens express P-glycoprotein. Two of these patients had tumors that were considered clinically drug resistant. No increase in P-glycoprotein expression was noted after exposure to chemotherapy, including the eight individuals for whom specimens were available both before and after treatment. Although drug resistance is a major problem in treatment of ovarian cancer, resistance to the drugs most active against these tumors probably occurs through a mechanism other than expression of the MDR1 gene product. (Am J Obstet Gynecol 1990;163:69-73.)

Key words: P-Glycoprotein, multidrug resistance, ovarian cancer, chemotherapy

Resistance to cytotoxic drugs by ovarian cancer cells is a major problem in the treatment of this disease. Approximately 75% of ovarian cancers respond initially to combination chemotherapy. The remaining 25% can be considered primarily resistant to chemotherapy. However, among the initial responders, all but approximately 15% to 20% of patients eventually have a relapse, with tumors subsequently displaying resistance to multiple chemotherapeutic agents. Thus some 80% of ovarian cancers are ultimately resistant to chemotherapy. Although the mechanisms of action of the various cytotoxic drugs are now fairly well understood, the mechanisms by which cancer cells are able to resist these effects are only beginning to be elucidated.

By means of tissue culture techniques, it has been observed that the exposure of tumor cells to relatively low concentrations of a particular cytotoxic agent may induce resistance not only to that agent but also to multiple other agents to which the tumor cells have never been exposed. This phenomenon has been termed multidrug resistance. One mechanism by which multidrug resistance may occur takes place at the level of the cell's plasma membrane. A high-molecular-weight glycoprotein, termed P-glycoprotein, has been found specifically associated with the plasma membrane in cells that display multidrug resistance, including some animal and human ovarian cancer cells,[1] where it may act as an energy-dependent efflux pump that removes toxic compounds from the cell. P-Glycoprotein is encoded by a gene, designated MDR1, that has homologies to other genes that encode membrane transport proteins. Monoclonal antibodies have been developed that detect P-glycoprotein in tissues, and preliminary reports have appeared examining its expression in human ovarian cancer.[2]

This study examines the expression of the MDR1 gene product in human ovarian cancers by means of monoclonal antibodies that detect P-glycoprotein, in an attempt to define the role this mechanism of drug resistance may play in ovarian cancer. Tumor specimens were further characterized with a panel of monoclonal antibodies representing a variety of epithelial cell antigens with known patterns of reactivity in ovarian cancer.[3]

Table I. P-glycoprotein expression of ovarian cancers by histologic cell type

Ovarian cancer cell type	Total		No. of patients with positive* specimens	
	No. of patients*	No. of specimens	MAB C219	MAB JSB-1
Serous	35	61	3	3
Serous borderline	3	3	0	0
Endometrioid	6	13	0	0
Clear cell	2	3	0	0
Mucinous	2	6	0	0
Undifferentiated	9	12	1	1
TOTAL	57	98	4	4

MAB, Monoclonal antibody.

*Many patients had multiple specimens tested from either the same operation or a subsequent procedure. Expression of P-glycoprotein did not vary among a given patient's specimens. Thus results are expressed by patient rather than by specimen.

Material and methods

Monoclonal antibodies. Murine monoclonal antibodies C219 (IgG2a) (Centocor, Malvern, Pa.) and JSB-1 (IgG1) (Bio/Can America, Portland, Maine), which recognize different internal epitopes of the P-glycoprotein molecule,[4, 5] were used as purified immunoglobulin at a concentration of 20 μg/ml or as diluted ascites (1:200), respectively. All tumor specimens were also characterized antigenically with a panel of monoclonal antibodies that included MH99 (IgG2a), MW162 (IgM), MX35 (IgG1), MW207 (IgG1), MT334 (IgG1), and A33 (IgG2a), all generated and characterized in our laboratory,[3] as well as OC125 (IgG1) (provided by Dr. R. Bast, Duke University).

Immunohistologic analysis. Tumor specimens were obtained at the time of laparotomy in 57 patients with epithelial ovarian cancer. Complete clinical information was available for all patients. Specimens were frozen in isopentane cooled in liquid nitrogen, embedeed in O.C.T. compound (Labtech, Naperville, N.C.), and stored at −70° C until cryosectioning. Tissue sections were cut at 6 μm, fixed for 10 minutes with cold acetone, and treated with 1% hydrogen peroxide to remove endogenous peroxidase activity. Detailed methods of the indirect immunoperoxidase technique have been described previously.[3] Briefly, tissue sections were incubated with monoclonal antibody for 90 minutes at room temperature, washed with phosphate-buffered saline solution, incubated with peroxidase-conjugated rabbit anti-mouse IgG (Dako, Santa Barbara, Calif.) for 60 minutes, and then washed again. The antigen-antibody complexes were visualized with diaminobenzidine (Sigma, St. Louis, Mo.) as the chromagen; Harris' hematoxylin was used as a counterstain. Sections were examined with a light microscope, and the antibody staining patterns were scored in a semiquantitative fashion.

Negative controls consisted of NS-1 culture supernatant or monoclonal antibodies of appropriate immunoglobulin class and subclass not reactive with ovarian tissue sections.

Results

A total of 98 specimens from 57 patients (stage I, 1; stage II, 7; stage III, 45; stage IV, 4) with epithelial cancers of the ovary were examined. These included tumor from 32 primary and 66 metastatic sites. Fifty-seven specimens were obtained from 33 patients previously untreated with chemotherapy; 11 specimens from eight of these patients were available after chemotherapy. An additional 30 specimens were studied from 24 other patients after chemotherapy for whom no pretreatment tissue was available. Postchemotherapy specimens were available from 19 patients who had been treated with one or more drugs specifically associated with selection of the MDR phenotype: doxorubicin (18 patients, mean eight courses), etoposide (2 patients, mean six courses), mitoxantrone (2 patients, mean six courses), vinblastine (1 patient, seven courses), and mitomycin (1 patient, five courses). Other chemotherapeutic agents used included cisplatin, cyclophosphamide, 5-fluorouracil, and others. The distribution of tumors analyzed in this study is shown in Table I by histologic cell type together with a summary of the staining results obtained with the two anti-P-glycoprotein monoclonal antibodies.

In only four of the 57 patients (7%) did one or more of the specimens express P-glycoprotein (Table II). All four patients had stage III disease. In two patients expression was detected at approximately the same level both before and after treatment with intravenous cisplatin and cyclophosphamide (one patient) and intravenous cisplatin and cyclophosphamide followed by intraperitoneal cisplatin (one patient). One patient was

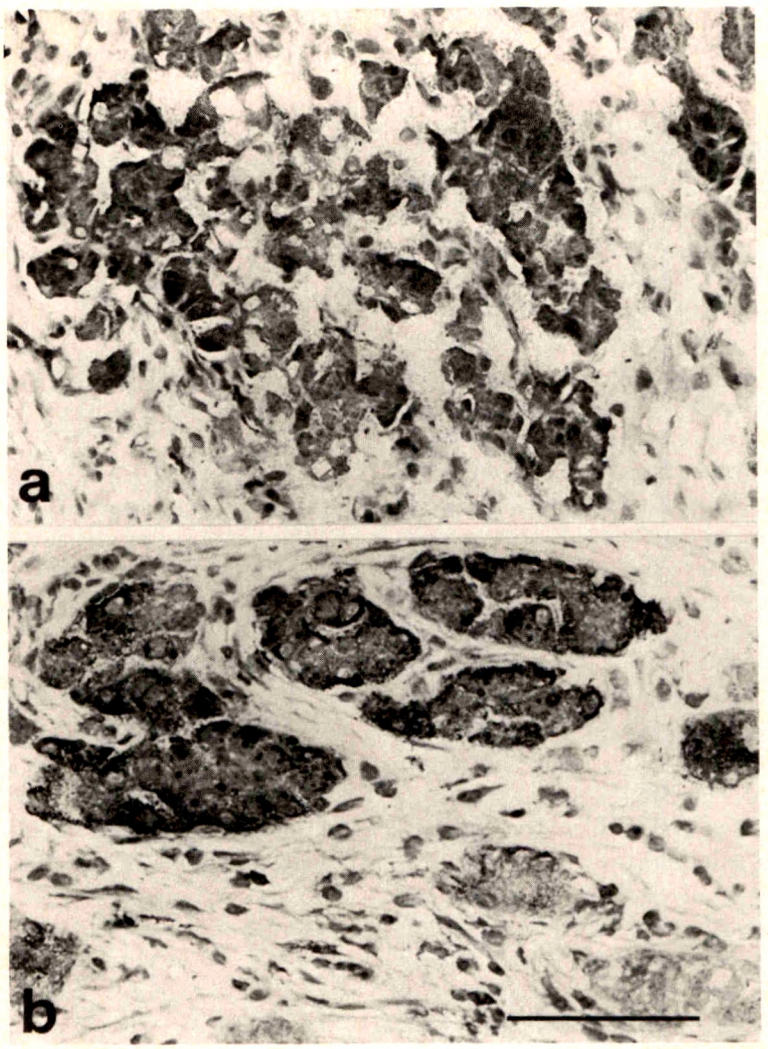

Fig. 1. Ovarian adenocarcinoma from patient No. 1 stained with monoclonal antibody C219 illustrating an apical membrane pattern of P-glycoprotein expression in the ovary **(A)** before chemotherapy and a colon nodule **(B)** after cyclophosphamide and cisplatin chemotherapy. Note weak heterogeneous pattern of staining in some but not all tumor cell islets **(B).** *Bar* = 100 μm.

considered clinically drug resistant; the other was not. Specimens from two other patients expressed P-glycoprotein at a high level in specimens obtained after treatment with the same drugs; specimens before treatment were not available. Disease in one of these patients was considered chemotherapy-resistant. A total of six specimens were examined from these four patients; expression of P-glycoprotein and expression of the other cell surface antigens studied did not vary among a given patient's specimens. No differences were observed between monoclonal antibody C219 and monoclonal antibody JSB-1 in the pattern of staining or in the number of positive specimens. Fig. 1 illustrates the staining pattern of a serous ovarian carcinoma from patient No. 1 before and after chemotherapy with mAbC219. Although the majority of the tumor cell islets stained with both antibodies, some islets were negative or showed heterogeneous expression with staining of individual tumor cells. The clinical characteristics of the patients with positive stains and the antigenic phenotypes of their tumors as determined by our panel of monoclonal antibodies are summarized in Table II. The tumor specimens from all four patients strongly expressed the antigens MH99, MW162, MX35, MW207, and CA125, which are characteristic of epithelial ovarian cancers and some other carcinomas. Specimens from three of the four patients also expressed MT334, a more restricted epithelial cell

marker that was detected in tumors from only 13 of the other 53 patients examined.

Comment

Use of the murine monoclonal antibodies C219 and JSB1, which detect different internal epitopes of the P-glycoprotein molecule, identified expression of P-glycoprotein in the tumors of only four of 57 (7%) patients with ovarian cancer, despite extensive investigation of multiple specimens from primary and metastatic sites before and after chemotherapy. No quantitative difference was observed in the staining pattern between the two antibodies. This low level of expression of P-glycoprotein in ovarian cancers is consistent with smaller studies from other investigators.[6, 7] This study, the first to examine P-glycoprotein expression in paired tumor specimens from the same patients both before and after chemotherapy, was unable to document any increase in expression of P-glycoprotein as a result of exposure to chemotherapy. Other studies that did not test paired specimens have suggested that this does occur as determined by measurement of MDR1 ribonucleic acid.[6, 7] In our material specimens from two of 33 untreated patients expressed P-glycoprotein, whereas specimens from four of 32 treated patients expressed P-glycoprotein. This difference was not statistically significant. Eight patients (two expressors) tested both before and after chemotherapy showed no change in tumor reactivity to P-glycoprotein. Significantly, no expression of P-glycoprotein was found in tumors from 19 patients exposed to chemotherapeutic drugs specifically known to cause selection of the MDR phenotype in vitro. This is in contrast to the findings of Bourhis et al.[7] who observed MDR1 ribonucleic acid expression in three of 10 patients treated with doxorubicin or vincristine and therefore suggested a role for P-glycoprotein in the acquired chemoresistance of ovarian cancer.

Given the widespread distribution of P-glycoprotein in normal human tissues,[8] it is possible that methods of detection that used electrophoresis of homogenized tissue to measure MDR1 deoxyribonucleic acid, ribonucleic acid, or protein, including Southern, Northern, and Western blotting, may overestimate the extent to which tumors express the MDR1 gene, as a result of contamination of tumor specimens with normal cells expressing P-glycoprotein. Similarly, it is possible that exposure to chemotherapy of the various nonmalignant cellular elements of tumor specimens, including stromal cells and blood cells, may result in increased expression of P-glycoprotein by these cells that could be interpreted by techniques that use homogenized tissue as increased tumor cell expression. Alternatively, it has been proposed that a subpopulation of P-glycoprotein–expressing tumor cells could be obscured by negative cells with these techniques. Methods that allow a more precise determination of P-glycoprotein expression at the cellular level, such as immunohistochemistry and in situ hybridization, may be more accurate in this regard.

Table II. Antigenic phenotype in four patients with epithelial ovarian cancer expressing P-glycoprotein

Patient No.	*Prior chemotherapy*	*Cell type and grade*	*Tumor sites*

*Monoclonal antibody reactivity was designated as follows: + + + +, homogenous reactivity; + + +, heterogeneous reactivity with 70% to 90% cells; + +, heterogeneous reactivity with 30% to 70% cells; +, heterogeneous reactivity with 10% to 30% cells; 0, negative.

†Indicates patient considered to have clinically drug-resistant disease on the basis of assessment of response at laparotomy.

Pharmacologic reversal of multidrug resistance has been reported in vitro with a variety of agents including verapamil, trifluoperazine, reserpine, quinidine, perhexiline maleate, anthracycline and vinca alkaloid analogs, and cyclosporine.[9-13] Dalton et al.[9] recently reported finding P-glycoprotein expression on tumor cells from six of eight patients with clinically drug-resistant multiple myeloma or non-Hodgkins lymphoma and demonstrated subsequent responses to chemotherapy in three of the eight patients when verapamil was added to the chemotherapy regimen. P-glycoprotein is apparently expressed in a small number of ovarian cancers, and expression has been reported to increase after exposure to chemotherapy,[6, 7] although we did not observe this in our study. Ozols et al.[14] were unable to demonstrate potentiation of the activity of doxorubicin by verapamil in eight patients with drug-resistant ovarian cancer, although the tumors had not been shown to express P-glycoprotein. Systemic toxicity of verapamil will limit its usefulness for this purpose. In vitro reversal of multidrug resistance in a doxorubicin-resistant breast cancer cell line has been

demonstrated with clinically achievable concentrations of toremifine, a tamoxifen analog likely to be well tolerated clinically.[15]

A recent report suggests that P-glycoprotein may be expressed in a small proportion of normal ovaries.[16] Its expression in occasional ovarian adenocarcinomas, which generally are derived from the surface epithelium of the ovary, may simply represent expression of a normal tissue differentiation antigen in a malignancy arising from that normal tissue.

Some women with epithelial ovarian cancer have tumors that are primarily chemotherapy resistant, and a large proportion of the others can be expected to manifest drug resistance in the future. Despite this, only a small proportion of these tumors express P-glycoprotein. It appears from this study that for the majority of patients with epithelial cancer of the ovary, resistance to the drugs most active against this cancer is mediated through mechanisms other than expression of the MDR1 gene product.

Large cystic granulosa cell tumor: Case report

Chang-Hyun M. Choi, MD, and James R. Pritchard, DO
Massillon, Ohio

This is a case of a large granulosa cell tumor of the ovary. The patient was a 42-year-old, white woman, gravida 1, para 1. The family claimed that she had a "water tumor" in her abdomen. The patient was afraid of seeing a doctor. She died at home without any medical attention. During autopsy we removed approximately 20 gallons of turbid reddish brown fluid from the cystic tumor. The tumor's cystic wall and the fluid weighed approximately 77 kg (170 pounds). No metastasis was found in any other organs. (Am J Obstet Gynecol 1990;163:74-6.)

Key words: Granulosa cell tumor, ovary

A case of a large granulosa cell tumor of the ovary is described. The woman failed to seek medical attention.

Case report

A 42-year-old white woman, gravida 1, para 1, was found dead in her apartment. During the last 3 days before her death, she had not moved at all and sat in a chair clutching a baby blanket. According to the family, they, along with the patient, noticed the growth in her girth 6 months previously but she failed to seek medical attention. Her medical history was unremarkable other than "not feeling good." She was not taking any medications. When the body arrived in the Stark County Coroner's morgue, an autopsy was performed.

The physical examination showed a well-developed, well-nourished white woman. The breasts were well developed and normal axillary and pubic hair was present. The upper extremities did not show pitting edema; however, the lower legs and feet revealed pitting edema (4+). The abdomen was extensively distended with the girth at the umbilicus measuring 168 cm (66 inches) (Fig. 1). The external genitalia were unremarkable. The skin on the back and abdomen showed irritated and eczematous changes.

From the Stark County Coroner's Office.

6/1/19485

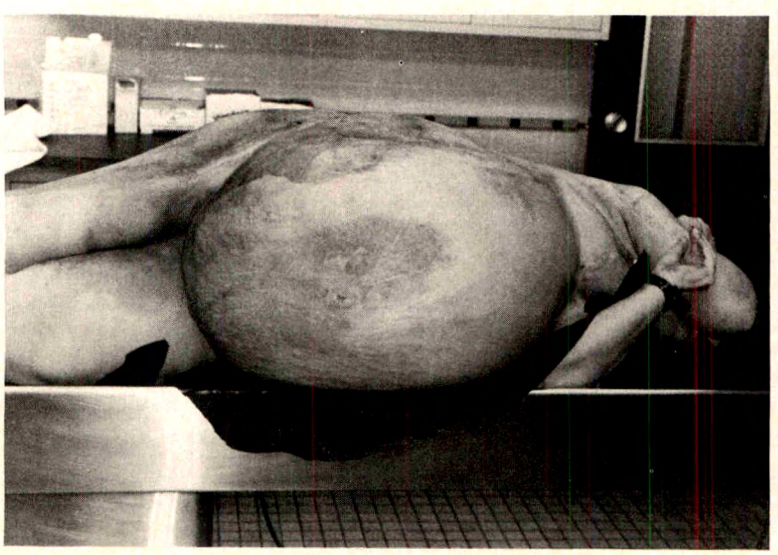

Fig. 1. Girth was 168 cm (66 inches), and approximately 76 L (20 gallons) of fluid was removed.

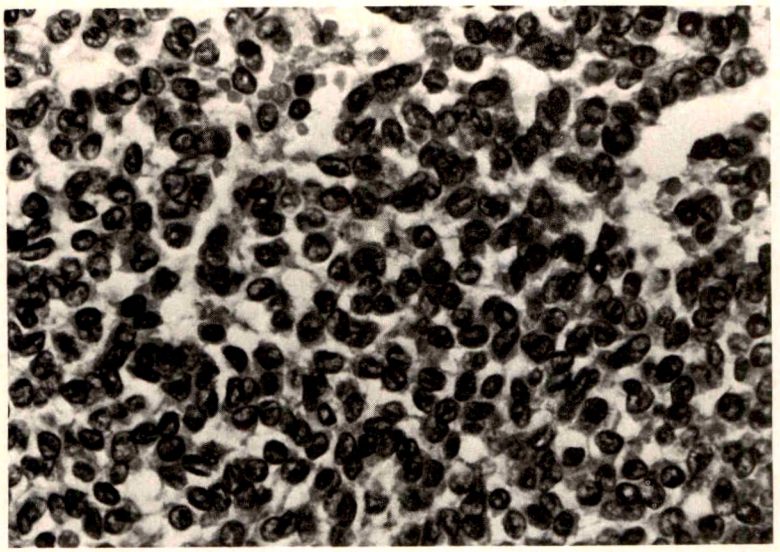

Fig. 2. Tumor cells have scanty cytoplasm. Nuclei are oval with prominent nuclear grooves (coffee bean–shaped nuclei). (Original magnification ×400.)

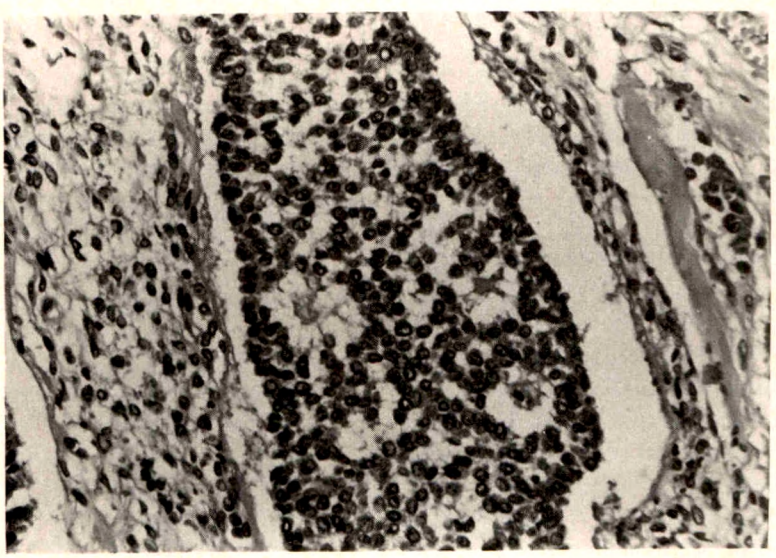

Fig. 3. Several Call-Exnar bodies are present. (Original magnification ×200.)

Before we opened the abdomen, the fluid was drained. There was approximately 76 L (20 gallons) of turbid reddish brown fluid. On opening the abdomen virtually the entire abdominal cavity and part of the pleural cavity were replaced by a cystic tumor mass. The inner surface of the cyst wall was necrotic, hemorrhagic, and irregular. The cyst measured approximately 56 cm (22 inches) in greatest diameter. The cyst wall measured 1 to 2 cm in thickness. The outer surface of the cyst was pink and glistening. The heart, lungs, and other organs were displaced and compressed by the large ovarian cystic tumor. The mass arose from the right ovary. The left ovary and uterus were within normal limits.

Histologically, the wall of the ovary and cyst showed oval hyperchromatic cells with scanty cytoplasm. Many cells showed nuclear grooves (coffee bean–shaped nucleus) (Fig. 2). Numerous Call-Exner bodies were present (Fig. 3). Sections from the endometrium showed adenomatous hyperplasia with focal cystic changes. The

tumor was probably functional because of the presence of adenomatous hyperplasia with focal cystic changes in the uterus. No other organs showed evidence of metastasis.

Comment

In 1939, Drs. Dockerty and McCartney[1] reported on large granulosa cell tumor of the ovary, which weighed approximately 35 pounds. In 1971, Drs. Robertson and Miller[2] reported on a massive cystic granulosa-theca cell tumor that weighed approximately 150 pounds. We describe almost the same size of tumor; however, ours is slightly larger than the most recent case. We believe our tumor is the largest recorded tumor of the same type.

We are grateful to Brenda L. Sherrod for providing assistance.

5-Fluorouracil exposure during the period of conception: Report on two cases

Lawrence D. Odom, MD,[a] Leo Plouffe, Jr., MD, CM,[a] and William J. Butler, MD[b]

Augusta, Georgia, and Albany, New York

Two patients who were administered topical vaginal 5-fluorouracil for human papilloma virus lesions became pregnant during treatment. The outcomes in both cases were healthy with normal developmental landmarks at 6 months of age. This experience highlights the potential for a positive outcome. (Am J Obstet Gynecol 1990;163:76-7.)

Key words: 5-Fluorouracil, periconceptual exposure

The incidence of lesions associated with human papillomavirus has increased dramatically in the past two decades. The treatment of these viral lesions has proved to be associated with recurrence in 10% to 35% of cases. Consequently, adjuvant or prophylactic use of 5-fluorouracil (5-FU) intravaginal therapy is becoming a widely accepted protocol. An obvious sequela of this new protocol is unexpected periconceptual exposure of the developing embryo to 5-FU, an antideoxyribonucleic acid chemotherapeutic agent. We present two cases of exposure during this period that resulted in two healthy, thriving infants.

Case report

Patient 1. A 26-year-old gravida 3, para 1-0-1-1 patient was first diagnosed and treated for genital condyloma at age 19 years. She had a history of regular 28-day cycles. Conization of the cervix was performed by laser vaporization after colposcopic examination and an abnormal biopsy specimen was obtained. The patient had daily application of approximately 65 mg of 5% 5-FU cream (Efudex, Roche Laboratories) to the vagina and cervix on cycle days 15, 16, and 17 for an estimated total of 185 mg of 5-FU. On approximately cycle day 31, the patient had positive results for β-human chorionic gonadotropin. By the last menstrual period and ultrasonographic evaluation, the embryo was exposed between conception cycle day 15 and cycle day 21. Level II ultrasonography at 21.1 weeks' gestation revealed a normal anatomic survey. The maternal serum α-fetoprotein level was 48 ng/ml or 1.6 multiples of the median. The patient was delivered by repeat cesarean section at term of a 3720 gm male infant with Apgar scores of 9 at 1 and 5 minutes. No anomalies were noted by a consulting pediatrician. The infant's developmental milestones have been uneventful at 6 months of age.

Patient 2. A 21-year-old gravida 1, para 0 patient was diagnosed with systemic lupus erythematosus at the age of 18 years. At that time the patient was given hydroxychloroquine sulfate and prednisone. At age 19 years, the patient had a colposcopically directed biopsy specimen diagnosis of cervical intraepithelial neoplasia, grade 2, and human papillomavirus infection. Her cycles at that time were regular and 28 to 30 days in length. After laser conization the patient received about 65 mg daily of adjuvant 5-FU intravaginal therapy on cycle days 18, 19, 20, and 21 for an appropriate total of 260 mg of 5-FU. On the basis of ultrasonographic evaluation and last menstrual period, exposure would have occurred at the time of conception. An ultrasonographic examination at 18.5 weeks' gestation revealed a normal anatomic survey. Although there was no evidence that a genetic amniocentesis would be informative, the patient elected to have this procedure performed. The results were: (1) 46,XY karyotype with no structural abnormality of the chromosomes; and (2) fetal α-fetoprotein = 9.4 μg/ml, which is within 2.3 multiples of the mean.

The patient had a normal vaginal delivery at term of a 3724 gm male infant with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. This infant had normal examination results at birth and normal developmental milestones at 21 months of age, as evaluated by a pediatric consultant.

Comment

The treatment of human papillomavirus–associated lesions is troublesome and lengthy for many women. Sillman et al. found incorporation of 5-FU maintenance therapy to be highly successful. Conception exposure incidence may be on the rise. Two cases of 5-FU exposure in pregnancy have been reported to date. Stephens et al.[1] reported multiple congenital anomalies in a fetus exposed to 5-FU during the first trimester and suggested that 5-FU may be a teratogenic agent. Stadler and Knowles[2] reported a case of intrauterine exposure to 5-FU at approximately 22 to 23 weeks' gestation that was subsequently interpreted as a case of neonatal intoxication.

It has been reported that 6% of a topically applied dose of 5-FU penetrates the skin in 24 hours. Diseased skin has been found to absorb approximately 15 to 75 times greater quantities of topically applied 5-FU than does normal skin. No evaluation with regard to vaginal absorption of 5-FU has been performed to our knowledge. Several investigators have shown that inert particles are easily and spontaneously transported from the vagina through the genital tract to the ovaries. Peripheral measurement of 5-FU would not be an accurate reflection of the true embryo exposure in the uterine or tubal lumen. Therefore the pharmacokinetic data outlined above may not be pertinent to vaginal 5-FU exposure, especially in the periconceptual period.

The preimplantation period is considered one when the embryo is invulnerable. This relates to the fact that in general the embryo will not be exposed to agents ingested by the mother until implantation. However, in the case of intravaginal 5-FU it is most likely that the embryo itself is in the fallopian tube and uterus at concentrations that exceed those circulating in the mother. The exact level cannot be quantitated.

We retain two possible explanations for the positive outcomes described here. One is that indeed 5-FU is a potent teratogenic agent. If the early embryo is affected, then a spontaneous loss will occur; otherwise the pregnancy will continue without associated complications. This all-or-none effect of early exposure to teratogenic agents is well described. Another possibility is that 5-FU exerts little or no teratogenic effect. It is likely that an uneventful ongoing pregnancy after periconceptual exposure will not display any adverse effects.

Detection of fetal blood contamination by amniotic fluid obtained during cordocentesis

Noam Lazebnik, MD, Paula V. Hendrix, MD, Graham G. Ashmead, MD, Josephine W. Ashmead, MD, and Leon I. Mann, MD

Cleveland, Ohio

When a fetal blood sample is obtained by cordocentesis it is important to know whether the sample is diluted with amniotic fluid. This study was designed to assess whether contaminated fetal blood samples could be discriminated from noncontaminated ones by the ferning test, and if so what is the minimum dilution ratio of amniotic fluid/fetal blood that is detectable. Fetal blood samples were diluted with amniotic fluid and were tested for ferning under the microscope after the plasma was separated from the cells. At a dilution ratio of 0.2 ml of amniotic fluid to 1 ml of fetal blood, 30% of the samples tested positive for ferning. A rate of 100% detection of ferning was achieved at a dilution ratio of 0.6:1. In conclusion, screening fetal blood samples for ferning can detect amniotic fluid contamination. The sensitivity of the test for ferning depends on the dilution ratio. The test cannot assess how much amniotic fluid was added to the blood sample. (AM J OBSTET GYNECOL 1990;163:78-80.)

Key words: Cordocentesis, fetal blood sampling, amniotic fluid contamination

Percutaneous umbilical blood sampling is gaining popularity as a method to test fetal blood samples for various clinical indications.[1] Some of the tests routinely done on fetal blood include the determination of fetal hemoglobin, hematocrit level, and other blood indices.[2] Once the needle is placed inside the umbilical artery or vein and the fetal blood sample is withdrawn, the tip of the needle may dislodge from the fetal vessel and amniotic fluid may contaminate the fetal blood sample. It is of utmost importance to know whether the fetal sample is diluted with amniotic fluid.

The following in vitro study was designed to test whether it is possible to detect amniotic fluid contamination of a fetal blood sample by the ferning test and if so, what is the minimum amniotic fluid/fetal blood dilution ratio that can be detected.

Material and methods

Amniotic fluid samples were collected after artificial rupture of the membranes on patients in active labor. We were careful not to use samples in which the amniotic fluid was grossly contaminated by maternal or fetal blood. After the neonate was delivered the cord was milked to obtain a fetal blood sample. A glass capillary was filled with the fetal blood and was centrifuged at 7000 rpm for 3 minutes to separate the serum from the cells. The hematocrit level of the sample was then determined and the plasma was spread on a glass slide and air dried. The sample was checked under the microscope for evidence of ferning.

The amniotic fluid was checked for evidence of ferning. After one drop was spread on a glass slide it was dried and checked with the microscope for ferning.

A given volume of the fetal blood sample was then diluted with the amniotic fluid starting with a dilution ratio of 0.1 ml of amniotic fluid to 1 ml of fetal blood. The dilution ratio was increased by increments of 0.1 ml up to a ratio of 1:1 and then a dilution of 2:1 was finally tested.

The diluted fetal blood samples were centrifuged at 7000 rpm for 3 minutes to separate the cells and the plasma. The plasma was spread on a glass slide, dried for 1 minute, and then examined under a microscope for evidence of ferning.

Results

A total of 10 fetal blood samples from 10 newborns were included in the study. The initial hematocrit level ranged from 44% to 58% (mean, 49.3% ± 7.8 SD).

None of the undiluted fetal blood samples tested positive for ferning under the microscope.

Table I presents the results of all fetal blood samples studied in the different dilution ratios. At a dilution ratio of 0.1 ml amniotic fluid to 1 ml fetal blood, only one sample showed evidence of atypical ferning. With increasing dilution ratios the number of samples that were positive for ferning increased. Even at lower ratios of 0.2:1, three of 10 samples tested positive for ferning. At a ratio of 0.4:1, 60% of the samples tested positive

Comment

The method proposed by us to determine amniotic fluid contamination of the fetal blood sample is based on the well known fact that amniotic fluid tests positive for ferning. The amniotic fluid forms an arborization (ferning) pattern when smeared on a clean slide and allowed to air dry. The phenomenon of ferning was first reported by Kardos and Tamasi.[3] This method has been used for years to detect rupture of the membranes. The reliability and utility of ferning have been confirmed by several reports.[4-7] On the other hand, fetal blood tests negative for ferning. Reece et al.[5] conducted an in vitro study to assess the effects of blood and meconium at various dilutions on the fern test. They concluded that the fern test was unaffected by meconium at any concentration and by blood at dilutions of ≥1:10. When blood and amniotic fluid were mixed in equal amounts, ferning was not present. It is very unlikely that maternal blood will be mixed with the fetal blood sample once the tip of the needle is placed in the umbilical vessel. Even if sufficient volume of maternal blood will find its way into the syringe, this would be identified by the Apt test or by testing the mean corpuscular volume of the blood sample.

The crystallization of the amniotic fluid, which is necessary for production of fern, or arborized pattern, is dependent on the concentration of electrolytes, principally sodium chloride, in the fluid. In general, a concentration of sodium chloride of 1% is required for the full development of a fern pattern; below that concentration either a beaded pattern or atypical incomplete arborization is seen. Theoretically any of the body fluids can form ferning including the perspiration from fingerprints, and this was reported to account for false-positive findings.[8]

We speculated that if fetal blood and amniotic fluid were mixed together we could detect the contamination of the fetal blood sample with amniotic fluid. Our results show two cases of atypical ferning at a diluton of 0.1:1. This atypical fern resulted from the fact that the sodium chloride concentration in the solution was too low to form typical ferning. However, at a dilution ratio of 0.2:1, 30% of the samples tested positive for ferning. At a dilution of 0.6:1 all samples tested positive for ferning. Whereas the specificity of the proposed test is 100% the sensitivity depends on the dilution ratio. At very low dilution ratios the sensitivity is only 30%. The sensitivity increased to 90% at a ratio of 0.5:1 and 100% at a ratio of 0.6:1. Therefore the proposed test may result in a false-negative result if the dilution is <0.6:1. The lower the dilution of the blood sample, the higher the rate of false-negative reading.

In our institution cordocentesis has been performed under a research protocol for the past 2 years. Fetal blood sampling to determine fetal hemoglobin and hematocrit level is the most common reason to perform the procedure. Regardless of the clinical indication for the procedure, all samples obtained by this procedure are tested for hemoglobin and hematocrit levels. Since the test was introduced in our fetal diagnostic unit three blood samples of 47 (6.4%) tested positive for ferns and the samples were repeated.

When the procedure is indicated in the presence of hemolytic disease, idiopathic thrombocytopenia purpura, fetal hydrops, and twin-to-twin transfusion, it is of the utmost importance to know whether the blood sample obtained was diluted by amniotic fluid. In cases of fetal anemia the result may determine whether there is an indication for an intrauterine fetal blood trans-

fusion. Once a decision is made to transfuse a fetus, the volume of blood transfused depends on the initial fetal hemoglobin level. If for any reason the fetal blood sample was diluted by amniotic fluid, the result will be falsely low, directly depending on how much amniotic fluid was accidently aspirated into the sampling syringe. If the result is too low, too much blood may be transfused into the fetus. Overtransfusion of the fetus could potentially result in fetal cardiovascular compromise, especially in a hydropic or severely stressed fetus.

One of the potential ways to overcome this problem is to look at the result of the other fetal cells counted (i.e., platelets and white blood cells). However, the range of these results may vary significantly from one fetus to another and one can never tell with certainty on the basis of cell counts whether small quantities of amniotic fluid were aspirated into the syringe. Only when the fetal white blood cell or platelet count is abnormally low without any apparent cause would one suspect that the fetal sample is diluted with amniotic fluid. The other way to make certain that the tip of the needle is in place is to flash the fetal vessel with saline solution after aspiration to be certain of placement. If after doing so there is uncertainty as to the location of the needle tip, we recommend the fern test.

In conclusion, amniotic fluid contamination of fetal blood sample may be detected if the sample is screened for ferning. The detection of ferning naturally cannot identify the dilution ratio of amniotic fluid to fetal blood hence, the true fetal blood hemoglobin cannot be determined. The fern test is an option that can be used as an aid in the determination of the presence of amniotic fluid in fetal blood samples.

Make researching easier with the Ten-Year Cumulative Index (1978-1987) to the American Journal of Obstetrics and Gynecology

The Ten-Year Cumulative Index is a complete guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the American Journal of Obstetrics and Gynecology from 1978 through 1987 (volumes 130 to 157). Numbering more than 800 pages, the Cumulative Index includes both a subject and an author index. This hard-cover volume is $64.50 ($69.00 international). Prices include shipping. *Payment must accompany all orders and must be in U.S. funds, drawn on a U.S. bank.*

Contact Mosby–Year Book, Inc., Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318 USA; phone (314) 872-8370, ext. 7394. In the U.S., call toll-free: 1-800-325-4177, ext. 7394. Please allow six weeks for delivery.

"It's still like walking the high wire, but now I have a safety net."

More confidence in presumptive antibiotic therapy. Prescribing UNASYN presumptively is a step you can take with confidence. UNASYN covers gram-positives (even enterococci), prevalent gram-negatives, and anaerobes: The right combination for most patients with common mixed infections.*

And UNASYN minimizes safety concerns with a reliable penicillin-class profile.[1] (However, UNASYN is contraindicated in penicillin-allergic patients.)

Expect strong support from UNASYN in the mixed infections* you face every day.

Life.

It's our life's work.

If your mission in life is to practice the ideals of medicine without administrative demands, we invite your inquiry.

Group Health Plan in St. Louis is a staff model HMO that promotes the ideals of private practice while freeing doctors from the financial baggage of the private practitioner.

Group Health Plan isn't for every physician. Just for those few who want to practice medicine without compromise.

For an interview please talk with the Medical Recruiter at (314) 993-5955. Or write Group Health Plan, 11475 Olde Cabin Road, St. Louis, Mo. 63141. An equal opportunity employer.

GROUP HEALTH PLAN

DOCTOR

WE HAVE YOUR LIFESTYLE

Practice in a place you've always wanted to live. Whatever your style, chances are we have the private practice opportunity to match it. After all, with over 80 hospitals in 20 states, we're very well connected. Here are just a few of your options:

Enterprise, AL	Kansas City, KS
Huntsville, AL	Louisa, KY
Montgomery, AL	Louisville, KY
North Alabama	Somerset, KY
Phoenix, AZ	New Orleans, LA
Denver, CO	Oakdale, LA
Central Florida	Springhill, LA
Dade City, FL	Natchez, MS
South Florida	Las Vegas, NV
St. Petersburg, FL	Chattanooga, TN
Atlanta, GA area	San Antonio, TX
Augusta, GA	Richlands, VA
Hoffman Estates, IL	Richmond, VA
Indianapolis, IN	Greenbrier Valley, WV

To find out about these and other opportunities, call TOLL-FREE 1-800-626-1590, or send your curriculum vitae to: Manager, Professional Relations, Humana Inc., Dept. QQ-7, 500 West Main Street, Louisville, KY 40201-1438.

INDICATIONS AND USAGE

UNASYN is indicated for the treatment of infections due to susceptible strains of the designated microorganisms in the conditions listed below.

Skin and Skin Structure Infections caused by beta-lactamase producing strains of *Staphylococcus aureus*, *Escherichia coli*,* *Klebsiella* spp.* (including *K. pneumoniae**), *Proteus mirabilis*,* *Bacteroides fragilis*,* *Enterobacter* spp.,* and *Acinetobacter calcoaceticus*.*

Intra-Abdominal Infections caused by beta-lactamase producing strains of *Escherichia coli*, *Klebsiella* spp. (including *K. pneumoniae**), *Bacteroides* spp. (including *B. fragilis*), and *Enterobacter* spp.*

Gynecological Infections caused by beta-lactamase producing strains of *Escherichia coli*,* and *Bacteroides* spp.* (including *B. fragilis**).

*Efficacy for this organism in this organ system was studied in fewer than 10 infections.

While UNASYN* (ampicillin sodium/sulbactam sodium) is indicated only for the conditions listed above, infections caused by ampicillin-susceptible organisms are also amenable to treatment with UNASYN due to its ampicillin content. Therefore, mixed infections caused by ampicillin-susceptible organisms and beta-lactamase producing organisms susceptible to UNASYN should not require the addition of another antibiotic.

CONTRAINDICATIONS

The use of UNASYN is contraindicated in individuals with a history of hypersensitivity reactions to any of the penicillins.

WARNINGS

SERIOUS AND OCCASIONALLY FATAL HYPERSENSITIVITY (ANAPHYLACTIC) REACTIONS HAVE BEEN REPORTED IN PATIENTS ON PENICILLIN THERAPY. THESE REACTIONS ARE MORE APT TO OCCUR IN INDIVIDUALS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY AND/OR HYPERSENSITIVITY REACTIONS TO MULTIPLE ALLERGENS. THERE HAVE BEEN INDIVIDUALS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY WHO HAVE EXPERIENCED SEVERE REACTIONS WHEN TREATED WITH CEPHALOSPORINS. BEFORE THERAPY WITH A PENICILLIN, CAREFUL INQUIRY SHOULD BE MADE CONCERNING PREVIOUS HYPERSENSITIVITY REACTIONS TO PENICILLINS, CEPHALOSPORINS, AND OTHER ALLERGENS. IF AN ALLERGIC REACTION OCCURS, UNASYN SHOULD BE DISCONTINUED AND THE APPROPRIATE THERAPY INSTITUTED.

SERIOUS ANAPHYLACTOID REACTIONS REQUIRE IMMEDIATE EMERGENCY TREATMENT WITH EPINEPHRINE. OXYGEN, INTRAVENOUS STEROIDS, AND AIRWAY MANAGEMENT, INCLUDING INTUBATION, SHOULD ALSO BE ADMINISTERED AS INDICATED.

PRECAUTIONS

General: A high percentage of patients with mononucleosis who receive ampicillin develop a skin rash. Thus, ampicillin class antibiotics should not be administered to patients with mononucleosis. In patients treated with UNASYN the possibility of superinfections with mycotic or bacterial pathogens should be kept in mind during therapy. If superinfections occur (usually involving *Pseudomonas* or *Candida*), the drug should be discontinued and/or appropriate therapy instituted.

Drug Interactions: Probenecid decreases the renal tubular secretion of ampicillin and sulbactam. Concurrent use of probenecid with UNASYN may result in increased and prolonged blood levels of ampicillin and sulbactam. The concurrent administration of allopurinol and ampicillin increases substantially the incidence of rashes in patients receiving both drugs as compared to patients receiving ampicillin alone. It is not known whether this potentiation of ampicillin rashes is due to allopurinol or the hyperuricemia present in these patients. There are no data with UNASYN and allopurinol administered concurrently. UNASYN and aminoglycosides should not be reconstituted together due to the *in vitro* inactivation of aminoglycosides by the ampicillin component of UNASYN.

Drug/Laboratory Test Interactions: Administration of UNASYN will result in high urine concentrations of ampicillin. High urine concentrations of ampicillin may result in false positive reactions when testing for the presence of glucose in urine using Clinitest™, Benedict's Solution or Fehling's Solution. It is recommended that glucose tests based on enzymatic glucose oxidase reactions (such as Clinistix™ or Testape™) be used. Following administration of ampicillin to pregnant women, a transient decrease in plasma concentration of total conjugated estriol, estriolglucuronide, conjugated estrone, and estradiol has been noted. This effect may also occur with UNASYN.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have not been performed to evaluate carcinogenic or mutagenic potential.

Pregnancy

Pregnancy Category B: Reproduction studies have been performed in mice, rats, and rabbits at doses up to ten (10) times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to UNASYN. There are, however, no adequate and well controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed. (See—Drug/Laboratory Test Interactions.)

Labor and Delivery: Studies in guinea pigs have shown that intravenous administration of ampicillin decreased the uterine tone, frequency of contractions, height of contractions, and duration of contractions. However, it is not known whether the use of UNASYN in humans during labor or delivery has immediate or delayed adverse effects on the fetus, prolongs the duration of labor, or increases the likelihood that forceps delivery or other obstetrical intervention or resuscitation of the newborn will be necessary.

Nursing Mothers: Low concentrations of ampicillin and sulbactam are excreted in the milk; therefore, caution should be exercised when UNASYN is administered to a nursing woman.

Pediatric Use: The efficacy and safety of UNASYN have not been established in infants and children under the age of 12.

ADVERSE REACTIONS

UNASYN is generally well tolerated. The following adverse reactions have been reported:

Local Adverse Reactions

Pain at IM injection site—16% Pain at IV injection site—3%
Thrombophlebitis—3%

Systemic Adverse Reactions

The most frequently reported adverse reactions were diarrhea in 3% of the patients and rash in less than 2% of the patients.

Additional systemic reactions reported in less than 1% of the patients were: itching, nausea, vomiting, candidiasis, fatigue, malaise, headache, chest pain, flatulence, abdominal distension, glossitis, urine retention, dysuria, edema, facial swelling, erythema, chills, tightness in throat, substernal pain, epistaxis and mucosal bleeding.

Adverse Laboratory Changes

Adverse laboratory changes without regard to drug relationship that were reported during clinical trials were:

Hepatic: Increased AST (SGOT), ALT (SGPT), alkaline phosphatase, and LDH.

Hematologic: Decreased hemoglobin, hematocrit, RBC, WBC, neutrophils, lymphocytes, platelets and increased lymphocytes, monocytes, basophils, eosinophils, and platelets.

Blood Chemistry: Decreased serum albumin and total proteins.

Renal: Increased BUN and creatinine.

Urinalysis: Presence of RBC's and hyaline casts in urine.

The following adverse reactions have been reported with ampicillin-class antibiotics and can also occur with UNASYN:

Gastrointestinal: Gastritis, stomatitis, black "hairy" tongue, enterocolitis and pseudomembranous colitis.

Hypersensitivity Reactions: Urticaria, erythema multiforme, and an occasional case of exfoliative dermatitis have been reported. These reactions may be controlled with antihistamines and, if necessary, systemic corticosteroids. Whenever such reactions occur, the drug should be discontinued, unless the opinion of the physician dictates otherwise. Serious and occasional fatal hypersensitivity (anaphylactic) reactions can occur with a penicillin (see WARNINGS).

Hematologic: In addition to the adverse laboratory changes listed above for UNASYN, agranulocytosis has been reported during therapy with penicillins. All of these reactions are usually reversible on discontinuation of therapy and are believed to be hypersensitivity phenomena.

ROERIG Pfizer
A division of Pfizer Pharmaceuticals

"I used to think only <u>two</u> things in life were certain."

Nothing comes closer to 100% activity against anaerobes in vitro. It's a fact. Studies have proved no other antibiotic superior to UNASYN in overall antianaerobic activity.[1-10] Not clindamycin. Not metronidazole. Nothing.

And that's nothing to overlook—given the importance of anaerobes in today's mixed infections.

Though clinical results may not always mirror those obtained in vitro, there's a world of confidence in choosing UNASYN for presumptive therapy of the mixed infections* you see every day.

Pregnancy Category B: Reproduction studies have been performed in mice, rats, and rabbits at doses up to ten (10) times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to UNASYN. There are, however, no adequate and well controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed. (See—Drug/Laboratory Test Interactions.)
Labor and Delivery: Studies in guinea pigs have shown that intravenous administration of ampicillin decreased the uterine tone, frequency of contractions, height of contractions, and duration of contractions. However, it is not known whether the use of UNASYN in humans during labor or delivery has immediate or delayed adverse effects on the fetus, prolongs the duration of labor, or increases the likelihood that forceps delivery or other obstetrical intervention or resuscitation of the newborn will be necessary.
Nursing Mothers: Low concentrations of ampicillin and sulbactam are excreted in the milk; therefore, caution should be exercised when UNASYN is administered to a nursing woman.
Pediatric Use: The efficacy and safety of UNASYN have not been established in infants and children under the age of 12.
ADVERSE REACTIONS
UNASYN is generally well tolerated. The following adverse reactions have been reported.
Local Adverse Reactions
Pain at IM injection site—16% Pain at IV injection site—3%
Thrombophlebitis—3%
Systemic Adverse Reactions
The most frequently reported adverse reactions were diarrhea in 3% of the patients and rash in less than 2% of the patients.
Additional systemic reactions reported in less than 1% of the patients were: itching, nausea, vomiting, candidiasis, fatigue, malaise, headache, chest pain, flatulence, abdominal distension, glossitis, urine retention, dysuria, edema, facial swelling, erythema, chills, tightness in throat, substernal pain, epistaxis and mucosal bleeding.
Adverse Laboratory Changes
Adverse laboratory changes without regard to drug relationship that were reported during clinical trials were:
Hepatic: Increased AST (SGOT), ALT (SGPT), alkaline phosphatase, and LDH.
Hematologic: Decreased hemoglobin, hematocrit, RBC, WBC, neutrophils, lymphocytes, platelets and increased lymphocytes, monocytes, basophils, eosinophils, and platelets.
Blood Chemistry: Decreased serum albumin and total proteins.
Renal: Increased BUN and creatinine.
Urinalysis: Presence of RBC's and hyaline casts in urine.
The following adverse reactions have been reported with ampicillin-class antibiotics and can also occur with UNASYN.
Gastrointestinal: Gastritis, stomatitis, black "hairy" tongue, enterocolitis and pseudomembranous colitis.
Hypersensitivity Reactions: Urticaria, erythema multiforme, and an occasional case of exfoliative dermatitis have been reported. These reactions may be controlled with antihistamines and, if necessary, systemic corticosteroids. Whenever such reactions occur, the drug should be discontinued, unless the opinion of the physician dictates otherwise. Serious and occasional fatal hypersensitivity (anaphylactic) reactions can occur with a penicillin (see WARNINGS).
Hematologic: In addition to the adverse laboratory changes listed above for UNASYN, agranulocytosis has been reported during therapy with penicillins. All of these reactions are usually reversible on discontinuation of therapy and are believed to be hypersensitivity phenomena.

ROERIG Pfizer

"We need gold-standard results that don't cost a fortune."

Lower antibiotic costs without lowering your standards. UNASYN costs at least 40% less per day than clindamycin/gentamicin or cefoxitin.[11] Yet UNASYN is at least as effective in a variety of mixed infections.*[3,12-19]

And in some studies versus combination therapy, patients treated with UNASYN spent fewer days in the hospital.[3,16,17]

So, look to UNASYN for highly effective, highly affordable therapy in mixed infections* every day.

Let our eminent medical authorities guide you through major new clinical advances

Introducing the

Year Book of Obstetrics & Gynecology®

This time-saving guide book makes it easy for you to keep current in your field. Each volume represents the year's most significant developments as reported in more than 800 journals and periodicals published worldwide. These selections are condensed to roughly a page in length, so you get all essential facts at a glance.

More importantly, the distinguished physician editors provide thoughtful, probing commentaries that explore the significance of each article while evaluating its practical implications for day-to-day practice.

Editors: Daniel R. Mishell, Jr., M.D.; Thomas H. Kirschbaum, M.D.; and C. Paul Morrow, M.D. **Contributing Editor**: William H. Hindle, M.D.

These books are published annually. For the convenience of its customers, Year Book enters each purchaser as a subscriber to future volumes and sends annual announcements of each volume approximately two months before publication. The new volume will be shipped upon publication unless you complete and return the cancellation notice attached to the announcement and it is received by Year Book within the time indicated (approximately 20 days after your receipt of the announcement). You may cancel your subscription at any time. The new volume may be examined on approval for 30 days and returned for full credit. Year Book will remove your name as a subscriber. Return postage is guaranteed by Year Book to the Postal Service.

Comparisons of glycosylated and nonglycosylated amniotic fluid prolactins in normal second- and third-trimester pregnancies

John McCoshen, PhD,[a] Eva Patalas, BSc(Med),[a] Edith Markoff, PhD,[b] David Lee, BSc,[b] and Yang Ming, MD[a]

Winnipeg, Manitoba, Canada, and La Jolla, California

Prolactins in glycosylated and nonglycosylated form were isolated from 218 second- and third-trimester amniotic fluid samples by sodium dodecyl sulfate–polyacrylamide gel electrophoresis, electrotransferred to nitrocellulose paper, and probed with anti–human prolactin serum and protein A labeled with iodine 125. The glycosylated and nonglycosylated prolactin bands were exposed by autoradiography. The bands were analyzed by densitometry, and the ratio of glycosylated to total (glycosylated + nonglycosylated) prolactin was calculated (glycosylated/total ratio) and compared with matched prolactin radioimmunoassay measurements. Both radioimmunoassay-measured and nonglycosylated prolactin decreased from the second to the third trimester whereas glycosylated prolactin concentrations remained unchanged. Concomitantly, glycosylated/total prolactin ratios increased significantly ($p < 0.001$). The correlation of radioimmunoassay-measured prolactin was closer to nonglycosylated prolactin ($r^2 = 0.32$, $p = 0.00001$) than to glycosylated prolactin ($r^2 = 0.02$, $p = 0.06$). We suggest that the proportion of amniotic fluid glycosylated prolactin increases with length of gestation and that glycosylation of prolactin is inversely related to total prolactin secretion. Furthermore, prolactin's immunoreactivity correlated more closely to the nonglycosylated-prolactin variant, suggesting that radioimmunoassay of prolactin poorly recognizes the glycosylated prolactin form. (Am J Obstet Gynecol 1990;163:81-5.)

Key words: Prolactin, glycosylation, amniotic fluid

Amniotic fluid prolactin (PRL) reaches peak levels in the second trimester of pregnancy and then decreases about fivefold by the third trimester.[1, 2] It originates in decidua and reaches the amniotic fluid by translocation across the fetal membranes.[3, 4] Two major molecular variants of PRL include the 23,000 molecular weight nonglycosylated moiety and a 25,000 molecular weight glycosylated form. Both are secreted by the pituitary gland and decidua and are normally present in the sera of men and nonpregnant women.[5-10] However, during pregnancy, when PRL concentrations increase, glycosylated PRL is particularly apparent.[6-8]

The profile of immunoassayable PRL in amniotic fluid is well delineated.[1-3] However, we know little concerning the glycosylated PRL variant and its physiologic significance in pregnancy. Radioimmunoassay (RIA) may detect only ≤30% of glycosylated PRL and, depending on the method used to measure bioactivity, purified glycosylated PRL is reported to have between 0% and 80% of the activity of nonglycosylated PRL.[9-12] Furthermore, with a specific antibody for glycosylated PRL not yet available, RIA measurements of PRL cannot discrminate between the glycosylated and nonglycosylated forms.[13]

In this study alternative analytic methods were used in conjunction with RIA, toward understanding the relationship between heterologous prolactins within the amniotic fluid compartment during the second and third trimesters of normal pregnancy.

Material and methods

Single amniotic fluid samples were obtained from the Fetal Assessment Unit and the Section of Clinical Genetics, University of Manitoba; these samples had been obtained by amniocentesis from 218 women who were subsequently proved to have genetically normal pregnancies and who had clinically normal pregnancy outcomes. Second-trimester amniotic fluid samples ($n = 194$) were obtained for genetic reasons, and third-trimester fluid samples ($n = 24$) were obtained either for assessment of fetal lung maturity ($n = 10$) or at the

6/1/21193

time of elective repeat cesarean section ($n = 14$). The study was approved before its commencement by the University of Manitoba Faculty Committee on the Use of Human Subjects in Research. The samples of fluid were stored at −20° C until assayed. Before assay, all samples were centrifuged to remove particulate matter. Subsequent to data collection, patient's charts were reviewed and the results of gestational age, karyotype, fetal assessment, and pregnancy outcome were recorded. The gestational age was determined at the time of amniocentesis by real-time ultrasonography and by calculation of the date of the last normal menstrual period.

RIA. The concentrations of PRL in amniotic fluid were measured in duplicate by RIA with a human PRL RIA kit from the National Institutes of Health. Intraassay and interassay variations were 6.8% and 10.6%, respectively.

Analysis of glycosylated and nonglycosylated PRL. To visualize glycosylated and nonglycosylated PRL as independent variants, samples of amniotic fluid were subjected to sodium dodecyl sulfate–polyacrylamide gel electrophoresis and immunoblot analysis as previously described.[8] Briefly, 10 μl aliquots of amniotic fluid were run on sodium dodecyl sulfate–polyacrylamide gel electrophoresis, electrotransferred to nitrocellulose paper, and probed with SB-3 anti–human PRL serum (generously supplied by Dr. S. Baxi, the Whittier Institute) and protein A. The bands were exposed by autoradiography. The measurements of glycosylated and nonglycosylated PRL levels were achieved by densitometric analysis of the autoradiographs. The positions of each PRL band were scanned in triplicate in each lane, and the mean density values were used to estimate the relative concentration in nondimensional units. Subsequently, the ratio of glycosylated to total PRL (glycosylated PRL + nonglycosylated PRL) was calculated for each lane and expressed as the glycosylated/total ratio. The interassay variation was determined from the glycosylated/total ratios in those lanes containing the purified glycosylated and nonglycosylated PRL standards ($n = 27$, mean = 0.156 ± 0.012 SD) and calculated to be 12.8%.

Statistical analysis. All data were analyzed according to gestational age and/or trimester. Statistical analysis included a parametric general linear model analysis of variance, the nonparametric Kruskal-Wallis test for group means, and simple and multiple regression analysis.

Results

A summary of the number of amniotic fluid samples obtained from each gestational age studied along with mean PRL concentrations is presented in Table I. Mean (±SEM) gestational ages of second- and third-trimester cases were 15.6 ± 0.1 and 38.2 ± 0.2 weeks, respectively. Peak levels of RIA PRL occurred at weeks 16 and 17. Mean (±SEM) RIA PRL concentrations (nanograms per milliliter) were 2766 ± 135 in the second trimester and 583 ± 74 in the third-trimester fluid. The distributions of the 23,000 nonglycosylated and 25,000 glycosylated PRL densities over gestational age are displayed in Fig. 1. As with the RIA PRL measurements, the summed nonglycosylated + glycosylated PRL densities reached peak levels over the sixteenth and seventeenth weeks and declined thereafter (data not shown). The nonglycosylated PRL–specific densities were highest during the same gestational ages while glycosylated PRL densities displayed little variation throughout gestation. Statistical analysis of these data revealed that RIA PRL, nonglycosylated + glycosylated PRL, and nonglycosylated PRL decreased significantly between trimesters, but glycosylated PRL did not (Table II); that is, the glycosylated PRL content failed to change significantly over gestational age or between trimesters. At the same time the relative proportion of glycosylated PRL to total (nonglycosylated + glycosylated) PRL, i.e., the glycosylated/total ratio, increased significantly as gestation progressed (Fig. 2). This necessarily resulted from the progressive decline in nonglycosylated PRL between the second and third trimesters accompanied by no significant change in glycosylated PRL over gestational age.

The comparison between RIA PRL measurements and glycosylated/total ratios is also represented in Fig. 2. The range of glycosylated/total ratios was 0.05 to 0.42. Correlation of RIA PRL to the glycosylated/total ratio was inverse ($r = -0.62, r^2 = 0.39$) and significant ($p = 0.02$). Thus high PRL concentrations appear to possess a proportionately lower glycosylated PRL component, suggesting that PRL heterogeneity is variable and concentration-dependent. Multiple regression analysis of RIA PRL concentrations versus nonglycosylated and glycosylated PRL had partial R^2 coefficients of 0.32 and 0.02, respectively, with probabilities of $p = 0.00001$ and $p = 0.06$. This indicated that RIA PRL measurements were more closely associated with the 23,000 nonglycosylated PRL form than with the 25,000 glycosylated PRL variant.

Comment

The profile of amniotic fluid PRL concentrations, as measured by RIA, was similar to that reported in other studies.[1, 2, 14] We found peak concentrations of immunoassayable PRL during the sixteenth to seventeenth weeks of gestation that subsequently declined approximately fivefold by the third trimester. In addition to PRL RIA, two major PRL variants were measured, including a 23,000 nonglycosylated PRL form and a

25,000 glycosylated variant that were assessed by densitometry. For each amniotic fluid sample the nonglycosylated and glycosylated PRL values were summed and a profile of calculated total PRL was compared to the values obtained by RIA. Both measurements produced similar profiles that were significantly correlated. However, segregation of the densitometry results revealed that RIA PRL values were more closely associated with the nonglycosylated PRL form than with the glycosylated PRL variant. Furthermore, while there was a significant decrease in both RIA and nonglycosylated PRL in the third trimester, there was no significant change in glycosylated PRL over the gestational ages or between trimesters. These data suggest that the RIA used is more sensitive to the nonglycosylated form than to the glycosylated variant. Furthermore, the results also may indicate that, on a unit volume basis, glycosylated PRL secretion into the amniotic fluid is in a relatively steady state throughout pregnancy. However, considering that there is a progressive increase in amniotic fluid volume between the second and third trimesters, total secretion of the nonglycosylated PRL variant may be in a steady state while that of glycosylated PRL increases. Alternatively, PRL glycosylation and/or deglycosylation may occur subsequent to PRL synthesis, or clearance rates may differ between the two forms.

Since the source of amniotic fluid PRL is the decidual lining of the uterus,[3, 4] the appearance of glycosylated PRL in amniotic fluid suggests that it too is a decidual product that gains access to the fluid cavity by transport across the reflected fetal membranes. Production of both nonglycosylated and glycosylated PRL forms by decidual tissue has been identified.[8]

Depending on the method used, the biologic activity of purified glycosylated PRL is reported to be between 0% and 80% of the activity of purified nonglycosylated PRL.[9-12] Furthermore, while sodium dodecyl sulfate–

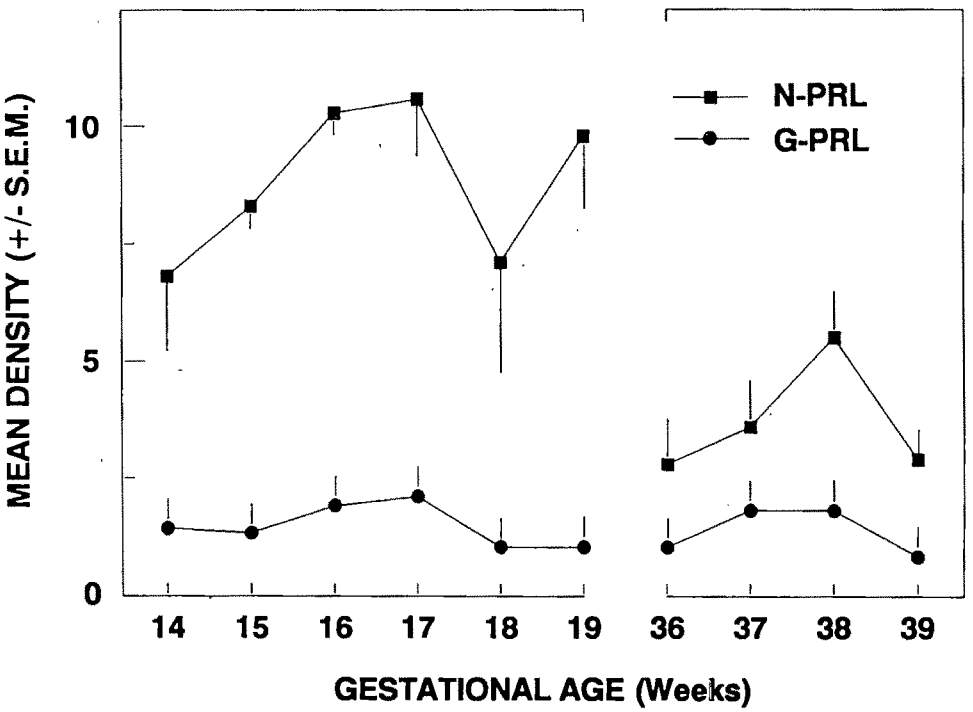

Fig. 1. Profiles of mean (±SEM) densities of nonglycosylated PRL *(N-PRL)* and glycosylated PRL *(G-PRL)* bands on immunoblot autoradiographs of normal second- and third-trimester amniotic fluid samples. *Break in border* segregates trimesters. *N-PRL*, but not *G-PRL*, significantly changed over age and between trimesters (see text and Table II for statistics).

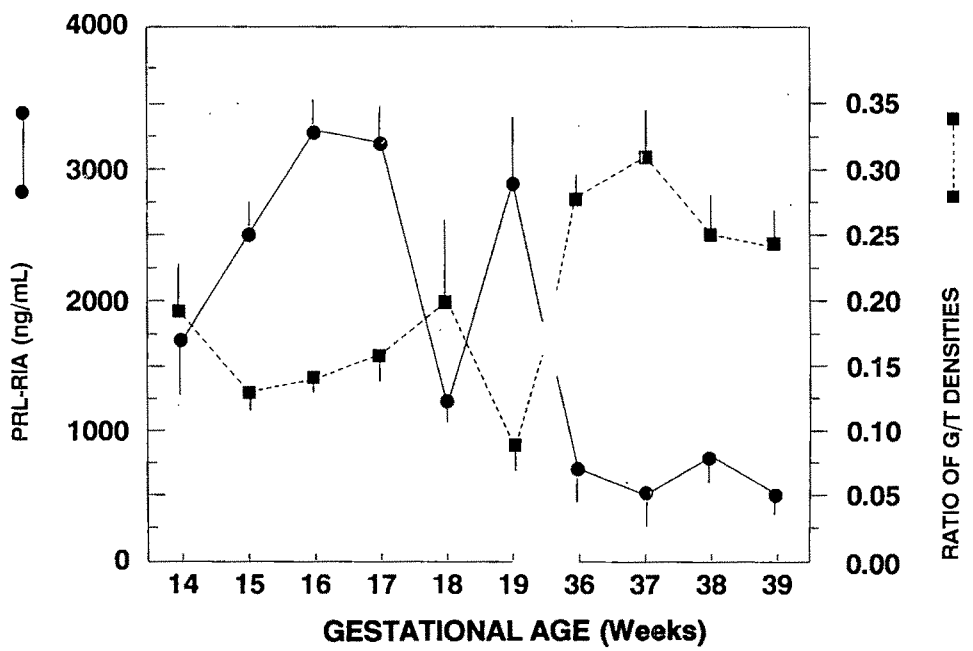

Fig. 2. Mean (±SEM) PRL RIA concentrations and ratios of glycosylated to total (glycosylated + nonglycosylated) PRL *(G/T)* in normal second- and third-trimester amniotic fluid. Break in lower border segregates trimesters. *G/T* ratio is inversely correlated ($r = -0.62, p = 0.02$) with RIA PRL concentration. RIA PRL significantly declined by third trimester while *G/T* ratio significantly increased (see text and Table II for statistics).

polyacrylamide gel electrophoresis immunoblots identified mean glycosylated PRL proportions of total PRL to be between 5% and 42%, we are still uncertain as to the total quantity of glycosylated PRL present in the amniotic fluid. RIA appears to detect only ≤30% of glycosylated PRL and is dependent on the anti–human PRL antibody used in the assay.[5, 13] We recently observed (unpublished observations), from protein stains of amniotic fluids run on sodium dodecyl sulfate–polyacrylamide gel electrophoresis, that the glycosylated PRL component of amniotic fluid actually may be in excess of the nonglycosylated form because of intense staining of the glycosylated PRL bands over those of nonglycosylated PRL, unlike that observed on immunoblots. Thus availability of an antibody specific to glycosylated PRL would allow more precise measurements of the total PRL present in both amniotic fluid and circulation.

Recently we reported that during normal pregnancy the biologic activity of amniotic fluid PRL increases between the second and third trimesters.[14, 15] In this study we found the proportion of glycosylated PRL also increased between the second and third trimesters. Since the biologic activity of glycosylated PRL in vitro is reported to be substantially less than that of the nonglycosylated PRL form,[9-12] our present findings suggest the paradox that glycosylated PRL may actually increase the overall biologic activity of amniotic fluid PRL. However, we have observed that the biologic activity of amniotic fluid PRL, as determined by the *Nb-2* lymphoma cell bioassay, may be mediated by human chorionic gonadotropin (McCoshen JA, Patalas E. Unpublished observations). Thus the biologic activity of amniotic fluid PRL may be a function of the proportion of the two major PRL variants, and specific production and activity of each variant may be under the influence of different factors.

In summary, these results identify nonglycosylated and glycosylated PRL variants in amniotic fluid. On a unit fluid-volume basis, nonglycosylated PRL paralleled PRL RIA values over time while glycosylated PRL did not. Thus the proportion of glycosylated PRL increases into the third trimester as total PRL declines. We speculate that secretion of the nonglycosylated and glycosylated PRL forms into the amniotic fluid may be controlled in part by different factors. Also, because of the poor correlation of PRL RIA results to glycosylated PRL measurements, we suggest that PRL RIA underestimates the total PRL content of amniotic fluid. Thus we speculate that the relative quantities of glycosylated and nonglycosylated PRL influence both concentration and bioactivity measurements that are important in determining the physiologic bearing of prolactin on pregnancy.

Glucose tolerance in pregnancy: Ethnic variation and influence of body habitus

James R. Green, MD,[a] Ivan G. Pawson, PhD,[b, c] Laurie B. Schumacher, MPH, PhD,[b, c, *] Jean Perry, MS,[a] and Norman Kretchmer, MD, PhD[a, b, c]

San Francisco, California

Little is known about ethnic differences in glucose tolerance during pregnancy. In this study we examined 3366 Hispanic, Chinese, black, and non-Hispanic white women in a universal screening program for gestational diabetes mellitus. After maternal age and body mass index were controlled, Chinese women had a significantly higher serum glucose level 1 hour after 50 gm of oral glucose (134.8 ± 1.2, mean ± SE) than any of the remaining three groups. Black women had a significantly lower value (113.3 ± 1.3, mean ± SE) than either Chinese or Hispanic women (124.4 ± 0.9, mean ± SE). Results for Hispanic women and non-Hispanic white women (121.4 ± 1.6, mean ± SE) were not different. The screening glucose levels of Chinese women were substantially higher than other ethnic groups even when women with gestational diabetes were removed from the analysis, indicating that the observed differences were not solely due to a higher frequency of gestational diabetes among the Chinese. The incidence of gestational diabetes was significantly greater for Chinese (7.3%) and Hispanic (4.2%) women than for black (1.7%) and non-Hispanic white (1.6%) women. Among women who had a 3-hour glucose tolerance test, the area under the glucose curve was significantly associated with maternal age and body mass index. The demonstrated heterogeneity of glucose tolerance between ethnic groups may be of importance in determining the threshold for diabetic fetopathy, and it is possible that ethnicity-specific standards will need to be developed. (AM J OBSTET GYNECOL 1990;163:86-92.)

Key words: Glucose tolerance, ethnicity, body habitus

Gestational diabetes mellitus is associated with a variety of complications of pregnancy, including macrosomia, birth trauma, and metabolic complications of the newborn.[1, 2] Gestational diabetes mellitus also appears to be a predictor of decompensated diabetes mellitus in later life.[3] It is currently recommended that all pregnant women be screened between 26 and 32 weeks of pregnancy with a 1-hour glucose determination after administration of 50 gm of oral glucose.[4] When the serum glucose level exceeds 140 mg/dl on this glucose load test, a 3-hour oral glucose tolerance test (GTT) should be performed with 100 gm of oral glucose. In the United States the GTT is usually interpreted according to criteria established by the National Diabetes Data Group.[5] On the basis of the studies of O'Sullivan and Mahan,[6] from which this screening protocol derives, the expected incidence of gestational diabetes mellitus is approximately 2.5%.

There is substantial variation in the reported incidence of gestational diabetes mellitus. In the series summarized by Hadden,[7] the incidence varied from 0.15% to 12.3%. At least three factors contribute to this variation. First, selection of only "high-risk" patients for testing will result in loss of sensitivity and incomplete ascertainment of the incidence of gestational diabetes mellitus.[7, 8] Second, standardization of test procedures is lacking. While the 100 gm GTT has gained wide acceptance in the United States, the 75 gm oral GTT recommended by the World Health Organization[9] is more commonly used elsewhere. The WHO criteria define impaired glucose tolerance as a 2-hour plasma value for glucose ≥140 mg/dl and gestational diabetes mellitus as a 2-hour plasma value for glucose ≥200 mg/dl.[9] Paired testing by the two protocols shows that their congruence is poor; the overall agreement is only 60%, and the WHO protocol appears to be a more stringent test.[10]

Constitutional, ethnic, and racial factors may further contribute to variation in the incidence of gestational diabetes mellitus. Women who have gestational diabetes

6/1/20570

mellitus are known to be older and heavier than women with normal glucose tolerance,[8,11] although it is not clear to what extent the effects of age and obesity are interrelated. Reliable estimates of the incidence of gestational diabetes mellitus in many ethnic or racial groups are lacking. The study by O'Sullivan and Mahan[6] on which National Diabetes Data Group standards are based, was conducted in an urban population consisting of predominantly non-Hispanic white (60%) and black (40%) women. In that study no differences were found between the races. Merkatz et al.[12] found a higher proportion of results in the upper ranges among non-Hispanic white women than among nonwhite women, although the incidence of gestational diabetes mellitus was similar in both studies. Other examples of apparent ethnic variation exist. The Pima Indians[13] have an incidence of gestational diabetes mellitus nearly 40 times that of the population studied by O'Sullivan and Mahan[6] and 10 times that of the population studied by Merkatz et al.[12] A recent study from Hong Kong[14] found a 13% incidence of gestational diabetes mellitus by the National Diabetes Data Group criteria among Chinese women who were selected for risk factors. Although this does not represent a population-based estimate, it is far higher than the rate of gestational diabetes mellitus among women with risk factors in other reports.[7]

Our early experience with a universal glucose screening program at San Francisco General Hospital suggested that there are substantial ethnic differences in the incidence of gestational diabetes mellitus. We were also interested in examining the influence of age and maternal body habitus on glucose tolerance in pregnancy. For these reasons we undertook a prospective study of glucose tolerance in pregnancy in a mutiethnic population, using a common standard for abnormality and without selecting subjects for high-risk factors.

Material and methods

Women who enrolled for prenatal care at San Francisco General Hospital or one of its satellite clinics before completion of thirty-two weeks of pregnancy were potential candidates for this study. The hospital serves predominantly women of low socioeconomic status; fewer than 5% have private health insurance. Since April 1983 it has been our policy to perform a 50 gm glucose test (glucose load test) on all prenatal patients between 26 and 32 weeks of pregnancy. Major risk factors for gestational diabetes mellitus prompt screening at an earlier point in pregnancy, with repeat testing in the early third trimester if that test result is negative. Women who are first seen for care after 32 weeks are not routinely screened, unless major risk factors are present. Between April 1983 and May 1986 a total of 4210 women underwent screening by this protocol. This number of subjects represents approximately 60% of the hospital's total prenatal population entering the third trimester of pregnancy during that period. The major reason for failing to screen was registration for care after 32 weeks. Acceptance of screening by both providers and patients was very good; once all the satellite clinics instituted the protocol, approximately 85% of potential subjects were screened successfully. The ethnic distribution of women who were screened and those who were not was very similar.

The great majority of glucose load tests were performed by a single individual. The tests were all performed during morning clinic sessions. Initially, patients were asked to fast overnight; during the latter phases of the study this requirement was relaxed, so that the woman did not eat for 2 hours before glucose was administered. The 50 gm of oral glucose was consumed within 5 minutes under direct observation, and the patient was asked not to eat, drink, smoke, or exercise during the subsequent hour. A specimen of venous blood was collected within five minutes of 1 hour after consumption of the glucose, and the serum was separated for analysis later the same day. The concentration of glucose was determined in the hospital's clinical laboratory by a standard automated hexokinase method.

During the study period the threshold for abnormality of the glucose load test was maintained at 150 gm/dl; it has subsequently been lowered to 140 mg/dl in compliance with more recent recommendations.[4] Women with abnormal results of the glucose load test were scheduled for a 3-hour GTT. After an overnight fast, a fasting serum glucose value was obtained and a 100 gm glucose load was given orally. Samples were drawn at 1, 2, and 3 hours after ingestion. Women were asked to refrain from eating, drinking, exercise, and smoking during this period of time. The threshold for abnormality of each of these specimens was as follows: Fasting, 105 mg/dl; 1 hour, 190 mg/dl; 2 hours, 165 mg/dl; 3 hours, 145 mg/dl. The GTT result was considered normal if none of the values met or exceeded the threshold. A single abnormal value constituted a "borderline" test, while two or more abnormal values were considered diagnostic of gestational diabetes mellitus.

At the time of the glucose load test, additional data were collected for the study and abstracted onto a data sheet. Maternal height and weight at the time of the glucose load test were confirmed. Patients were characterized as obese if weight-for-height exceeded 120% of ideal, when adjusted for expected pregnancy weight gain by locally generated curves. Self-reported prepregnancy weight was recorded; however, fewer than 20% of patients actually had access to scales at home, and this value was felt to be unreliable. Maternal body

Table I. Overall results of screening program

Ethnic group	*n*	*%*	*Abnormal glucose load test*	*Abnormal GTT*
Hispanic	1,943	46.2	16.2	4.2

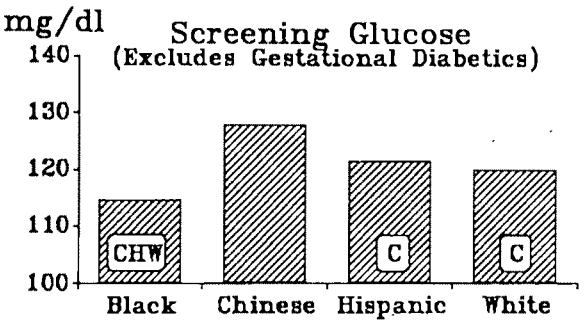
IBW, Ideal body weight.

mass index (kilograms per square meter) was calculated from height and weight at the time of screening. Maternal ethnicity, as self-identified, was recorded into more than 50 categories. These categories were combined into nine major groups for the purpose of this analysis. To simplify statistical analysis, we included only the first glucose load test for each individual that was performed between 26 and 32 weeks' gestation. Women with pregestational diabetes and those receiving β-adrenergic receptor agonist therapy for management of preterm labor or asthma were excluded. For women undergoing a GTT, the area under the glucose curve was calculated with a standard formula: Glucose area = (Fasting + 1 hour + 2 hour + 3 hour) − 0.5 (Fasting + 3 hour).

Data were analyzed with a general linear models approach to determine the roles of maternal age and body mass index in glucose tolerance. A two-way analysis of variance was used to examine interaction between ethnicity and the independent variables. Pairwise comparisons were made between the ethnic groups, and adjusted means were calculated for the dependent variables by setting the value of each covariate at its mean.

Results

Table I shows the ethnic variation in the incidence of abnormal results of glucose load tests and GTTs for the entire screened population. There was marked variation in the incidence of abnormal glucose load tests. A particularly high incidence was observed among Chinese and Filipino women. Pacific Islander and Middle Eastern women also had a high percentage of abnormal glucose load test results, although the number of women in these groups was too small to analyze. In contrast, a very low incidence of abnormality was seen in black women. Non-Hispanic white and Hispanic women had an intermediate incidence of abnormality. Although the numbers of Native Americans were quite small, it is interesting to note that the incidence of abnormal screening test results was low. The incidence of gestational diabetes mellitus among the ethnic groups followed a similar pattern in most respects. Chinese, Filipino, and Middle Eastern women had the highest incidence of gestational diabetes mellitus. Hispanic women were intermediate, while black and non-Hispanic white women had the lowest incidence. The latter group had the highest false-positive rate for glu-



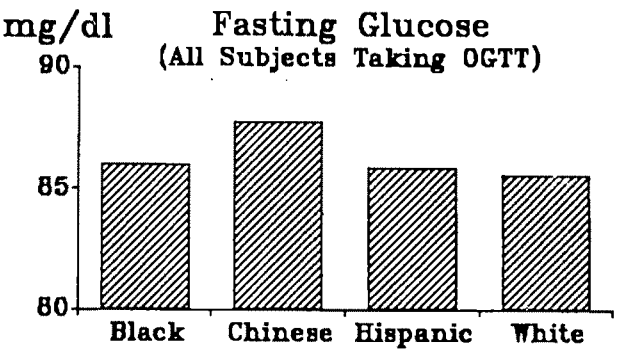


Fig. 1. Adjusted values of screening glucose by ethnic group. *Top,* Includes women with gestational diabetes; *bottom,* excludes women with gestational diabetes ($p < 0.05$).

cose load test results when judged by the results of the GTT. No cases of gestational diabetes mellitus were identified among the small numbers of Native American women in our population.

The subsequent analysis was limited to the four largest ethnic groups: Chinese, Hispanic, black, and non-Hispanic white. Chinese and Hispanic subjects were grouped on the basis of language. The "Chinese" sample is relatively homogeneous, deriving from the Han populations in southern China, as well as Chinese-speaking individuals from mainland China, Taiwan, and Hong Kong. The "Hispanic" sample comprises Spanish-speaking individuals from Mexico and various Central and South American countries. The degree of admixture with black and non-Hispanic white is not known.

Table II shows demographic variables for these four groups. Values are noted as significantly different at $p < 0.05$. Chinese women were significantly older than women in the remaining three groups, while black women were significantly younger. Non-Hispanic white and Hispanic women were close in age, but the difference was still significant.

Body size and proportionality differed significantly between the four groups. Chinese mothers were significantly lighter in weight than black, Hispanic, and non-Hispanic white mothers, and Hispanic women were significantly lighter than both black and non-Hispanic white women. Chinese and Hispanic women were significantly shorter than black and non-Hispanic white mothers. Chinese women had a significantly lower body mass index than the other three groups. Non-Hispanic white women had a significantly lower body mass index than either black or Hispanic women. Chinese and non-Hispanic white mothers had significantly lower parity than either black or Hispanic mothers. The black and Hispanic samples had the highest number of obese women; the Chinese sample had the lowest number of obese women.

Table III details the results of the screening program for the four major ethnic groups. Fig. 1 illustrates the comparisons of the adjusted means for each ethnic group. Where adjusted mean values differ, the letter of the ethnic group (*C* for Chinese, *B* for black, *W* for non-Hispanic white, and *H* for Hispanic) whose adjusted mean value is significantly larger ($p < 0.05$) is shown in the column for the ethnic group with the smaller value. Chinese women had a higher screening

*Adjusted for maternal age and body mass index.

serum glucose level than any other group ($p < 0.0001$). Black women had a significantly lower screening serum glucose value than Chinese or Hispanic women ($p < 0.0001$). The screening serum glucose values for non-Hispanic white and Hispanic women were not significantly different. After adjustment for maternal age and body mass index, the mean screening blood glucose level for Chinese women still remained significantly higher than that for the other three ethnic groups ($p < 0.0001$), and that for black women remained significantly lower than that for Hispanic and Chinese women ($p < 0.0001$). To examine whether this result was due to a larger number of cases of gestational diabetes in the Chinese sample or to a real difference in screening glucose values between the ethnic groups, we repeated the analysis for calculating adjusted means excluding women with gestational diabetes (two or more abnormal values on GTT) from all the ethnic groups. As Fig. 1 illustrates, when cases of gestational diabetes were removed from the sample, black women had significantly lower screening glucose values than Chinese, Hispanic, and non-Hispanic white women ($p < 0.0001$). Hispanic and non-Hispanic white women had significantly lower screening glucose values than Chinese women ($p < 0.0001$) when women with gestational diabetes were removed from the analysis.

A total of 588 women in these four groups underwent a GTT (Table III). The proportion of abnormal GTT results was significantly higher in Hispanic and Chinese women than in black and non-Hispanic white women. Non-Hispanic white women had a lower proportion of abnormal test results than any of the three remaining groups. Chinese women had significantly higher total areas under the curve ($p < 0.05$) (Fig. 2). When the area under the curve was adjusted for age and body mass index (Table III), Chinese women still had a significantly higher total glucose area than either Hispanic or non-Hispanic white women. In those women who had an abnormal GTT result (Table III), there were no significant differences in the total area under the glucose curve between the ethnic groups. Black women had significantly higher unadjusted fasting glucose values (Table III) than any of the remaining groups, as well as a higher proportion of fasting glucose levels >105 mg/dl. In contrast, Chinese women had significantly lower values for unadjusted fasting glucose and a significantly lower proportion of results over the threshold for abnormality. The results for Hispanic and non-Hispanic white women were similar (Table III). Fig. 2 illustrates adjusted fasting glucose values for women having a GTT. Chinese women had the highest values, while black, Hispanic, and non-Hispanic white women had similar values. None of these values were significant.

Comment

This study demonstrates differences in glucose tolerance in pregnancy between four ethnic groups studied. Since maternal variables of age and body habitus were controlled for in the analyses, ethnic differences

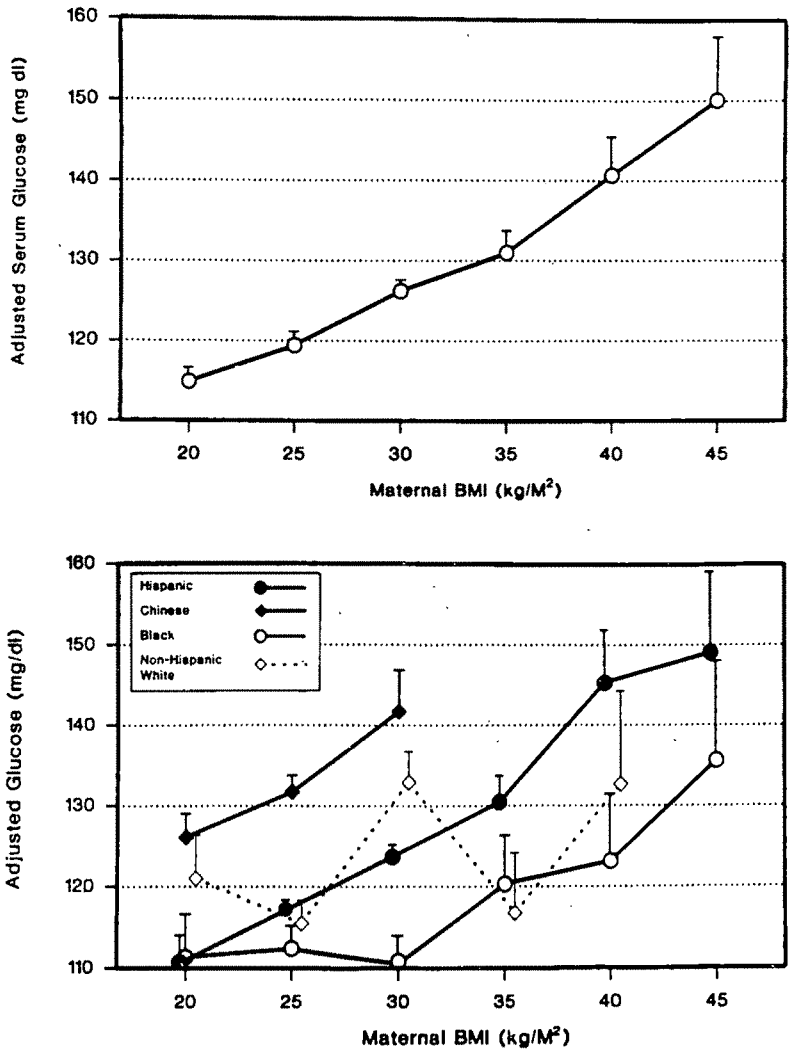

Fig. 3. *Top,* Adjusted screening glucose level by maternal body mass index, all ethnic groups combined. For each body mass index stratum the data point represents the least-square mean (+1 SEM) derived from an analysis of covariance with age and ethnic group controlled. *Bottom,* Adjusted screening glucose by maternal body mass index group in Hispanic, Chinese, black, and non-Hispanic white women. For each body mass index stratum the data point represents the least-square mean (+1 SEM) derived from an analysis of covariance with age and ethnic group controlled.

were not explained by these factors. In a separate regression analysis performed for each ethnic group individually, age and body habitus were significantly associated with deterioration of glucose tolerance, particularly for Chinese women. Evidence of worsening glucose tolerance with advancing age was found in all four ethnic groups, with a trend toward more age-related deterioration in black than in non-Hispanic white women. These findings are consistent with previous reports[8, 11, 12] and support the concept that many women with gestational diabetes have the potential for the development of diabetes after delivery.

The screening glucose levels of Chinese women were substantially higher than those of other ethnic groups when matched for body mass index. Chinese women had significantly higher screening glucose values even when women with gestational diabetes were removed from the analysis. These data support the hypothesis that results from the screening test results are clearly different between the ethnic groups and that these differences are not due to a higher frequency of gestational diabetes among the Chinese.

Obesity is an acknowledged risk factor for the development of both gestational diabetes mellitus and diabetes in later life.[8, 11] In the present study all four ethnic groups showed some evidence of worsening glucose tolerance with increasing body mass index, but the response was not entirely uniform. Chinese and Hispanic

women exhibited more marked deterioration (Fig. 3) in glucose tolerance with increasing body mass index than did black women until a state of moderate obesity was reached. It is possible that glucose intolerance in black women is relatively immune to the effect of mild to moderate obesity. In contrast, there was marked deterioration of glucose tolerance in both the Hispanic and Chinese groups with even mild obesity. We do not know if the pattern of obesity, even mild obesity, is important in the risk of diabetes mellitus among gravid women. This question deserves further investigation in light of recent studies linking fat patterns with diabetes mellitus in adults.[15]

This study does not address directly the issue of standards for the oral GTT in pregnancy. The definition of abnormality for the National Diabetes Data Group criteria was based on 95% confidence limits of unselected oral glucose load test results in non-Hispanic white and black women.[6] On the basis of a comparison of Israeli and U.S. populations, Friedman et al.[16] argue that the standards for abnormality should be adjusted for both ethnic and age factors. In effect, this approach would maintain the incidence of gestational diabetes mellitus constant across dissimilar groups. Such an approach presumes that the fetus responds relative to some ethnic and/or constitutional "norm" rather than according to an absolute threshold of glucose abnormality. There is no direct evidence to support this concept. Therefore, despite our finding of significant ethnic differences, the validity or necessity of constructing "ethnicity-specific" test thresholds remains to be demonstrated.

The threshold of glycemia for diabetic fetopathy in late pregnancy is not known and may not be constant for all morbidities. Moreover, if such a threshold exists, it may be substantially modified by other factors, including the coexistence of obesity. It has been argued that the National Diabetes Data Group standards are too "liberal" and that morbidity is better predicted by the WHO criteria.[14] Conversely, it has been argued that even women with a single abnormal value on a 3-hour GTT have evidence of increased neonatal morbidity.[17, 18] In the study by Langer et al.,[17] black and white women with a single abnormal value on oral GTT were compared with matched control subjects who had either gestational diabetes mellitus or normal oral GTT results. The incidence of neonatal abnormalities (particularly the incidence of macrosomic infants and the metabolic abnormalities including polycythemia) was significantly increased with one abnormal value. It is unclear if glucose tolerance has an impact on the pattern of fetal growth and whether maternal obesity and ethnicity are important covariables. Until such relationships are better understood, arguments about the threshold for abnormal glucose tolerance in late pregnancy will remain largely moot.

Gestational diabetes mellitus: The prevalence of glucose intolerance and diabetes mellitus in the first two months post partum

Siri L. Kjos, MD,[a] Thomas A. Buchanan, MD,[b] Jeffrey S. Greenspoon, MD,[a] Martin Montoro, MD,[a] Gerald S. Bernstein, MD,[a] and Jorge H. Mestman, MD[a]

Los Angeles, California

To determine the prevalence of abnormal carbohydrate metabolism in the early postpartum period in women with gestational diabetes mellitus, we performed 2-hour oral glucose tolerance tests between 5 and 8 weeks post partum in 246 women with recent gestational diabetes mellitus. Patients were stratified into three study groups based on their fasting serum glucose level during pregnancy: (1) group A_1: all fasting serum glucose levels during pregnancy <105 mg/dl without insulin therapy; (2) group A_2: any fasting serum glucose levels >105 and <140 mg/dl before insulin therapy; (3) group B_1: any pregnancy with fasting serum glucose levels >140 mg/dl. Overall, 48 (19%) of the patients had an abnormal oral glucose tolerance test in the early postpartum period; 25 (10%) had impaired glucose tolerance and 23 (9%) had diabetes mellitus. The prevalence of postpartum diabetes mellitus (2% in group A_1, 9% in group A_2 and 44% in group B_1) increased in parallel with the degree of maternal metabolic decompensation during pregnancy ($p < 0.05$ for A_1 versus A_2; $p < 0.001$ for A_2 versus B_1). The prevalence of impaired glucose tolerance was likewise greater in the B_1 group (26%) than in either the A_1 or the A_2 group ($p < 0.05$). Gestational age <24 weeks at diagnosis of gestational diabetes mellitus was an additional risk factor for postpartum glucose intolerance. Our findings support the use of an oral glucose tolerance test in the early puerperium, especially for patients with elevated fasting serum glucose levels during pregnancy. (Am J Obstet Gynecol 1990;163:93-8.)

Key words: Gestational diabetes, glucose tolerance, non-insulin-dependent diabetes

Gestational diabetes mellitus is currently defined as "carbohydrate intolerance of variable severity with onset of first recognition during the present pregnancy."[1, 2] This definition does not restrict the severity of carbohydrate intolerance, nor does it exclude possible pregestational or postpartum glucose intolerance. Indeed, existing data suggest that women with gestational diabetes may have had undiagnosed glucose intolerance before pregnancy[3] and frequently have abnormal glucose tolerance within the first year post partum.[4-6] These patients also have an increased risk of overt diabetes later in life.[7-13] The appropriate time to begin detection of glucose tolerance abnormalities in women with prior gestational diabetes mellitus has not been defined. Because most patients have a routine postpartum examination approximately 5 to 8 weeks after delivery, we reasoned that this might be a useful time to test patients for glucose intolerance. Therefore we performed this study to determine the prevalence of abnormal carbohydrate tolerance between 5 and 8 weeks post partum in women with recent gestational diabetes mellitus. Furthermore, we attempted to relate the prevalence to the severity of metabolic decompensation during pregnancy, as indexed by fasting serum glucose levels. Finally, we examined maternal age, body mass index, and gestational age at the time of diagnosis as possible predictors of abnormal postpartum glucose tolerance.

Material and methods

Subjects. During 1987, the period of this study, 16,363 women were delivered of their infants at Los Angeles County–University of Southern California Women's Hospital. Most were referred from 16 local prenatal care clinics. In accordance with the Second International Workshop-Conference on gestational diabetes mellitus,[2] prenatal clinic patients undergo a serum glucose determination 1 hour after a 50 gm oral glucose load between 24 and 28 weeks of gestation, or on entry if prenatal care commenced after 28 weeks. Women who are seen before 24 week with one or more risk factors for gestational diabetes mellitus (history of macrosomia, prior gestational diabetes mellitus, prior stillbirth, glycosuria, maternal obesity, hypertension,

Table I. Mean age and postpartum body mass index of women with gestational diabetes mellitus stratified according to antepartum fasting glucose levels*

Study group	*Age (yr)*	*Body mass index (kg/m²)*
A_1 (n = 100)	30 ± 1	29 ± 1
A_2 (n = 123)	30 ± 1	30 ± 1
B_1 (n = 23)	30 ± 1	32 ± 1

BMI, Body mass index.

*A_1, A_2, and B_1 denote women with antepartum fasting serum glucose levels <105, 105 to 139, and >139 mg/dl, respectively. Numbers in parentheses denote the number of women in each group. Body mass index denotes body weight/(height)². None of the differences between group mean values was statistically significant.

family history of diabetes, or maternal age >35 years) were screened at their initial visit and again at 24 to 28 weeks' gestation. Patients with a 1-hour glucose screen ≥140 mg/dl underwent a 3-hour, 100 gram oral glucose tolerance test (GTT) in accordance with national Diabetes Data Group guidelines.[1] Women with gestational diabetes mellitus had weekly fasting serum glucose determinations; postprandial serum glucose levels were not measured. Women whose fasting serum glucose levels were consistently <105 mg/dl were managed with diet therapy alone. Those who had two fasting serum glucose values ≥105 mg/l, or those with any fasting serum glucose level ≥140 mg/dl were treated with diet and insulin. Insulin therapy was not required in any patients during the puerperium. Subjects for this study were recruited at the time of delivery at Women's Hospital. The study was approved by the Research Committee of the Los Angeles County–University of Southern California Medical Center.

Postpartum testing. After 3 days of a diet that provided at least 150 gm/day of carbohydrate, patients fasted overnight (10 to 16 hours), then ingested 75 gm of glucose over 5 minutes. Serum specimens were obtained by repeated venipuncture at −5, +30, +60, +90, and +120 minutes. Specimens were transported on ice for immediate separation of serum and cells. Serum was stored at −20° C for subsequent glucose measurement (Glucose Analyzer II, Beckman Instruments, Fullerton, Calif.). Postpartum glucose tolerance results were interpreted according to National Diabetes Data Group criteria.[1] Some women had postpartum oral GTT results that fit neither the normal nor the impaired category in the National Diabetes Data Group classification. We included these subjects in the normal category for the purposes of data analysis because they did not have sufficient hyperglycemia to warrant classification as impaired glucose tolerance.

Data analysis

Subject classification. Patients were stratified by their degree of metabolic decompensation during pregnancy, as indexed by the initial fasting serum glucose of their antepartum oral GTT and by their fasting serum glucose levels before insulin therapy. Three study groups were defined: group A_1: all patients with fasting serum glucose levels <105 mg/dl without insulin therapy, group A_2: any patient with a fasting serum glucose ≥105 mg/dl and <140 mg/dl before any insulin therapy, and group B_1: any patient whose fasting serum glucose was ≥140 mg/dl (Table I).

Statistical analysis. Data are presented as mean ± SE. The statistical significance of differences among the three study groups with respect to categoric variables (i.e., postpartum glucose tolerance status, antepartum study classification, and gestational age at diagnosis ≤24 or >24 weeks) was determined with χ^2 or Fisher's exact test. Statistical significance was assessed after adjusting for multiple comparisons when appropriate. The relationship between continuous variables (age, body mass index, or pregnancy fasting serum glucose) and postpartum glucose tolerance status was assessed by analysis of variance or, if the data were not normally distributed, by the Kruskal-Wallis test. When these tests revealed significant difference in distribution of means among groups, the Tukey's multiple comparison procedure was used to identify intergroup differences.

Results

Patient classification. In 1987, 525 women with the diagnosis of gestational diabetes mellitus were interviewed in the immediate postpartum period and scheduled for follow-up evaluation of carbohydrate tolerance between 5 and 8 weeks post partum. Of these, 274 women kept their follow-up appointments, and underwent a postpartum oral GTT between 5 and 8 weeks after delivery. Twenty-eight of these patients were excluded from analysis because their antepartum oral GTT results were incompletely documented. Thus 246 patients were included in the final analysis. Ninety-eight percent of these patients had Spanish surnames.

Of the 246 study patients, 100 (41%) were classified as belonging to group A_1, 123 (50%) as A_2, and 23 (9%) as B_1 (Table I). The distribution of classes among the 251 women who did not return for a postpartum oral GTT was similar: 35% in group A_1, 51% in A_2, and 14% in B_1 ($p > 0.2$ compared with the 246 study patients).

Body mass index (kg/m²) was determined at the time of the postpartum oral GTT. Overall, 74% of the patients were obese (body mass index ≥27). Each of the three study groups had a mean body mass index indicative of obesity (Table I). There were no significant

differences in body mass index among the groups. Likewise, mean age did not differ significantly among groups (Table I).

Postpartum glucose tolerance. Overall, 81% of patients had normal or unclassifiable oral GTT results between 5 and 8 weeks post partum. An additional 10% had impaired glucose tolerance and the remaining 9% had diabetes mellitus. The proportions of women with normal, impaired, and diabetic oral GTTs in each of the three antepartum groups appear in Table II. The majority (90%) of the 100 women in the A_1 group had normal postpartum glucose tolerance. Only 8% of these women had impaired glucose tolerance and an additional 2% had diabetes mellitus. Of the 123 women in the A_2 group, 101 (82%) had normal early postpartum carbohydrate tolerance. Half of the remaining 22 women (9% overall) had impaired glucose tolerance, similar to the 8% prevalence of impaired glucose tolerance in the A_1 group. However, an additional 9% of the A_2 group had diabetes mellitus in the puerperium, a prevalence that was significantly greater than that of the A_1 group ($p < 0.03$).

Both diabetes mellitus and impaired glucose tolerance were common in the B_1 group post partum. Of the 23 women in that group, only seven (30%) had normal glucose tolerance in the early puerperium. Six (26%) had impaired glucose tolerance, and 10 (44%) had diabetes mellitus. Statistical analysis revealed that the prevalence of diabetes mellitus ($p < 0.01$) and of impaired glucose tolerance ($p < 0.05$) post partum was each greater in the B_1 than in either the A_1 or the A_2 group. Thus marked fasting hyperglycemia during pregnancy (class B_1) was associated with an increased risk of both diabetes mellitus and impaired glucose tolerance in the puerperium. Less severe fasting hyperglycemia during pregnancy (class A_2) was also associated with an increased risk of diabetes mellitus but not with impaired glucose tolerance compared with women without fasting hyperglycemia during pregnancy.

The gestational age at time of diagnosis of gestational diabetes mellitus was examined as another possible predictor of abnormalities in postpartum glucose tolerance. As expected from the design of our antepartum screening program for gestational diabetes mellitus, the majority (203/246 or 82%) of cases were diagnosed during or after the twenty-fourth week of gestation (Table III). Only 43 (18%) were diagnosed before this time. However, those women diagnosed before 24 weeks had a significantly greater prevalence of abnormal oral GTTs in the early puerperium than did women diagnosed after 24 weeks (44 versus 14%; $p < 0.001$).

To determine whether elevated antepartum fasting serum glucose levels and an early gestational age at diagnosis imparted independent risks of abnormal glucose tolerance postpartum, we used multivariate analysis to compare the distributions of antepartum fasting serum glucose levels and of gestational age at diagnosis among the three postpartum glucose tolerance categories (Table IV). After adjustment for the effects of gestational age at diagnosis, antepartum fasting serum glucose levels in women with normal and impaired glucose tolerance post partum were slightly, but not significantly, different (101 ± 2 and 113 ± 5 mg/dl, respectively). The antepartum fasting serum glucose levels in women with postpartum diabetes mellitus (144 ± 5 mg/dl) were significantly higher than in the normal and impaired glucose tolerance groups ($p < 10^5$). Similarly, after adjustment for the effects of fasting serum glucose, gestational ages at diagnosis of gestational diabetes mellitus in women with postpartum impaired glucose tolerance and diabetes mellitus were not different (25 ± 1 and 24 ± 1 weeks, respectively) but were significantly less than in women with normal glucose tolerance post partum (30 ± 1 weeks; $p < 0.003$). Thus we found elevated FSG levels and an early gestational age at the diagnosis of gestational dibetes mellitus to be independent risk factors for abnormal glucose tolerance in the puerperium.

We found no significant differences in mean age (30 ± 1, 30 ± 1, and 29 ± 1 years, respectively) or body mass index (30 ± 1, 31 ± 1, and 31 ± 2 kg/m,^{2} respectively) among groups with normal, impaired, and diabetic glucose tolerance post partum.

Fasting serum glucose in the detection of postpartum diabetes. The diagnosis of diabetes in nonpreg-

Table II. Prevalence of normal, impaired, and diabetic glucose tolerance test results in women with recent gestational diabetes mellitus*

FSG, Fasting serum glucose level; *IGT,* impaired glucose tolerance; *NIDDM,* non-insulin-dependent diabetes mellitus.

**Antepartum FSG* denotes the initial fasting serum glucose level obtained during the antepartum oral GTT or, in the case of patients first seen with a fasting serum glucose level ≥ 140 mg/dl, the initial fasting serum glucose level obtained. The statistical significance of differences in the prevalence of diagnoses between groups is denoted.

†$p < 0.001$ versus normal and impaired glucose tolerance.

‡$p < 0.01$ versus impaired glucose tolerance and non-insulin-dependent diabetes mellitus.

nant adults can be based on fasting serum glucose levels ≥140 mg/dl, a sufficiently abnormal oral GTT, or both.[1] With the fasting serum glucose levels obtained at the time of postpartum oral GTTs, we examined the utility of a fasting serum glucose level ≥140 mg/dl in detecting diabetes in our nonpregnant patients. Of the 23 women who met diagnostic criteria for non-insulin dependent diabetes mellitus postpartum, only seven (30%) had a fasting serum glucose level ≥140 mg/dl at the time of their postpartum oral GTT. The remaining sixteen women (70% overall) would have escaped detection by screening for a fasting serum glucose level ≥140 mg/dl in the early puerperium. We further analyzed our data to determine whether there was a level of fasting glycemia in the puerperium below which the diagnosis of early postpartum diabetes mellitus was unlikely. We found that 20 of the 23 women with postpartum diabetes mellitus had fasting glucose levels >115 mg/dl. However, the remaining three women with postpartum diabetes mellitus had fasting serum glucose levels <105 mg/dl.

Comment

The primary objective of this study was to determine whether routine glucose tolerance testing at 5 to 8 weeks post partum in women with recent gestational diabetes mellitus would detect an important number of women with abnormal glucose tolerance after pregnancy. We also sought to identify maternal characteristics that would place women at particularly high risk for diabetes in the puerperium. Therefore at the time of delivery we recommended early postpartum glucose tolerance testing to 525 women with gestational diabetes mellitus. Approximately half the women returned for the recommended testing. The fact that we could identify no differences in the distribution of gestational diabetes mellitus cass (A_1, A_2, and B_1) between the women who did and those who did not return for testing suggests that those who did return were not self-selected for any particular risk of diabetes of impaired glucose tolerance post partum. Of the 243 women who did return for early postpartum testing, approximately one in five had an abnormal oral GTT result; half of these met current diagnostic criteria for non-insulin-dependent diabetes mellitus. Thus glucose tolerance was clearly abnormal in many of our patients soon after delivery. This finding supports the proposition of Harris[3] that abnormal glucose tolerance may actually antedate pregnancy in some women with gestational diabetes mellitus. As detailed by Metzger et al.,[6] this may be particularly true for women with marked hyperglycemia during pregnancy.

Because most of our patients had normal glucose tolerance at 5 to 8 weeks post partum, we examined several factors that we thought would identify the high-risk women most appropriate for early postpartum glucose tolerance testing. We found that an elevated maternal fasting serum glucose level during pregnancy and an early gestational age at diagnosis of gestational diabetes mellitus were associated with an increased risk of diabetes mellitus and impaired glucose tolerance in the puerperium. With regard to fasting serum glucose data, nearly 10% of women with fasting glucose levels of 105 to 139 mg/dl during pregnancy had diabetes within 5 to 8 weeks of delivery; 44% of our patients with fasting serum glucose levels ≥140 mg/dl during gestation had diabetes in the puerperium. These fast-

ing serum glucose results are consistent with the pattern reported by Metzger et al.[6] within 1 year after delivery and seem to indicate that the metabolic derangement(s) that lead to fasting hyperglycemia during pregnancy are not specific for gestation. Rather, it appears that an elevated fasting serum glucose level during pregnancy is a marker for underlying metabolic abnormalities that may have preceded pregnancy,[3] which are clearly present in some women very soon after delivery, and that predict a high likelihood of diabetes in later life.[8]

The threefold increase in the prevalence of postpartum oral GTT abnormalities in women diagnosed with gestational diabetes mellitus before 24 weeks' gestation may have been a function of the protocol currently used to detect gestational diabetes. Women were tested before 24 weeks only if they had risk factors for gestational diabetes mellitus. Some of these risk factors (e.g., obesity and a family history of diabetes) are also risk factors for nonpregnant diabetes. The women diagnosed before 24 weeks' gestation were thus a select minority of patients with known risk factors for diabetes outside of pregnancy. This may explain their increased risk of postpartum glucose tolerance abnormalities. We found neither maternal age nor postpartum body mass index to be useful predictors of abnormal glucose tolerance in the puerperium, perhaps because our patients were rather homogeneous with regard to these two variables.

The prevalence of glucose tolerance test abnormalities in our patients with recent gestational diabetes mellitus is lower than that reported by Metzger et al.[6] within 4 to 12 months after delivery. Several factors may have contributed to this difference. First, we used a smaller glucose challenge (75 gm) than did those authors (100 gm). Probably more important is the earlier time after delivery at which we studied our patients. Clinical experience indicates that insulin requirements fall very quickly after delivery. The fact that many women with pregestational diabetes require little or no insulin in the early puerperium suggests that insulin action may actually be better postpartum than it was before conception. The time course of return to a prepregnancy equilibrium in carbohydrate metabolism, if this in fact occurs, is unknown. Therefore it is possible that we examined women at a time when their glucose tolerance was optimized. Our continued follow-up should reveal whether the incidence of diabetes and impaired glucose tolerance in our Hispanic patients at 6 to 12 months post partum truly differs from that reported by Metzger et al.

What is the relevance of our findings to clinicians caring for women with gestational diabetes mellitus? First, we suggest that women with fasting serum glucose levels $\geq$140 mg/dl during pregnancy should have an oral GTT at their initial postpartum visit because we found that 44% of these women had diabetes at that time. Second, in view of the 9% prevalence of diabetes mellitus and the additional 9% prevalence of impaired glucose tolerance in women with less marked fasting hyperglycemia (105 to 139 mg/dl) during pregnancy, we suggest that these women be tested at 5 to 8 weeks post partum. Finally, the 2% prevalence of diabetes mellitus and 8% prevalence of impaired glucose tolerance in the women with recent A_1 gestational diabetes mellitus suggest that routine glucose tolerance testing also be done in this group. Although most women in this last group will have normal oral GTTs soon after pregnancy, initiating a program of testing in the puerperium stresses the importance of periodic (e.g., annual) glucose tolerance testing at a time when their attention is focused on diabetes. Detection of diabetes in women who have the disease will allow the initiation of treatment with diet, medications, or both at a time when clinically apparent microvascular and neuropathic complications generally do not exist. Furthermore, documentation of abnormal carbohydrate tolerance aids in family planning recommendations.

We thank Rebecca Burt, Norma Chavez, and the physicians and the nurses of the Family Planning Clinic at Los Angeles County Women's Hospital for their help in recruiting and studying patients, and Mary Stabler and Gladys Mosley for their technical assistance.

Indomethacin treatment for polyhydramnios and subsequent infantile nephrogenic diabetes insipidus

Leon G. Smith, Jr., MD, Brian Kirshon, MD, and David B. Cotton, MD
Houston, Texas

A case of polyhydramnios was effectively treated with amniotic fluid decompression and indomethacin. Six months later nephrogenic diabetes insipidus was diagnosed and indomethacin was again effectively used. By reducing urine output, indomethacin controlled both in utero and extrauterine polyuria in this patient. (AM J OBSTET GYNECOL 1990;163:98-9.)

Key words: Polyhydramnios, indomethacin, diabetes insipidus

In a case reported by Kirshon and Cotton,[1] polyhydramnios was documented in a fetus with an extra unidentified marker chromosome. By reducing fetal urine output, indomethacin was successfully used to prevent reaccumulation of amniotic fluid after therapeutic amniocentesis. A clinical association was established between a chromosomal abnormality, an extra marker chromosome, and polyhydramnios. However, the exact cause of the polyhydramnios remained unknown until 6 months after delivery. The infant was discovered to have nephrogenic diabetes insipidus. We report here a retrospective analysis of polyhydramnios caused by nephrogenic diabetes insipidus and its overall management.

Case report

A 33-year-old gravida 3 now para 3-0-0-3 physician with no previous medical problems was hospitalized for abdominal distention and pain at 26 weeks' gestation. Her prenatal evaluation was normal except for a maternal serum α-fetoprotein level <0.4 of the median at 16 weeks' gestation. On admission a level II ultrasonographic examination showed a singleton, structurally normal fetus with polyhydramnios. Amniocentesis was performed for both chromosomal analysis and therapeutic decompression. Cytogenetic studies showed a 47,XX+ marker chromosome pattern in all 20 cells examined. The extra marker chromosome was a small ring chromosome of unknown origin. Peripheral blood studies performed after birth confirmed the presence of the ring chromosome in 70% of cells, whereas 30% showed a normal 46,XX chromosome pattern.

After removal of 3000 ml of amniotic fluid, indomethacin was initiated at 25 mg orally every 4 hours to control both preterm labor and to prevent reaccumulation of polyhydramnios. A marked diminution of fetal urine output was observed by serial ultrasonographic evaluations. Fetal echocardiography failed to show constriction of the ductus arteriosus. Indomethacin therapy was continued until 35 weeks' gestation. One week later spontaneous labor ensued, and a 2280 gm female infant with Apgar scores of 9 at 1 and 5 minutes was vaginally delivered. There were no apparent physical abnormalities of the neonate.

The infant was subsequently noted to be a poor feeder and consequently was admitted to the hospital at 6 months of age for failure to thrive. Significant physical findings included a dehydrated and irritable infant with a temperature of 101° F. Pertinent laboratory data included serum osmolality 305 mosm/L, urine osmolality 98 mosm/L, urine specific gravity 1.003, serum sodium 150 mEq/l, and urine sodium 13 mEq/L, confirming the presence of diabetes insipidus. The serum blood urea nitrogen and creatinine concentrations were 20 mg/dl and 0.3 mg/dl, respectively.

6/1/19897

A vasopressin challenge test failed to show a change in urine or serum osmolality. Results of a renal ultrasonographic examination were essentially normal. On the basis of the above information, the diagnosis of nephrogenic diabetes insipidus was made. On the sixth hospital day, indomethacin therapy was started at 2 mg/kg per day, resulting in a decrease in serum osmolality from 305 to 290 mosm/L, a decrease in serum sodium from 150 to 135 mEq/L, a 50% decrease in urine output, and an increase in urine osmolality from 98 to 140 mEq/L. At discharge the infant was well hydrated and was gaining weight. Sixteen months later, the child remains on indomethacin therapy, and her renal function (as measured by serum creatinine concentration) has remained normal. The child has not shown any adverse effects of indomethacin treatment.

Comment

The diagnosis of congenital nephrogenic diabetes insipidus in the infant was evident by (1) a history of polyhydramnios as a result of fetal polyuria in utero, (2) no underlying disorders such as obstructive uropathy known to cause nephrogenic diabetes insipidus, and (3) a low urine osmolality unresponsive to vasopressin. Therefore a fetus with polyhydramnios should be carefully examined at birth for electrolyte imbalances, even when a clinical association such as a chromosomal abnormality has been established. Congenital nephrogenic diabetes insipidus should be considered as a possible cause of polyhydramnios.

Although the exact mechanism for the antidiuretic action of indomethacin is unknown, this case serves to show the efficacy of indomethacin both in reducing antenatal fetal urine output and in treating polyhydramnios as well as controlling infantile nephrogenic diabetes insipidus.[2]

We are grateful to David Ledbetter, PhD (Kleberg Cytogenetics Laboratory, Houston, Tex.) for his helpful discussion and support.

Risk factors for third-degree and fourth-degree perineal lacerations in forceps and vacuum deliveries

C. Andrew Combs, MD, PhD, Patricia A. Robertson, MD, and Russell K. Laros, Jr., MD
San Francisco, California

Third- and fourth-degree perineal lacerations occur frequently during operative vaginal deliveries. To identify risk factors for lacerations, 2832 consecutive forceps and vacuum extraction deliveries were analyzed. Third- and fourth-degree lacerations occurred in 30% of deliveries. Multiple logistic regression was used to control for intercorrelation between potential risk factors. Factors associated with increased risk for third- and fourth-degree lacerations were midline episiotomy, nulliparity, second-stage arrest, occipitoposterior position, low or mid station, use of forceps instead of vacuum, use of local anesthesia, and Asian race. When these factors were controlled, there was no effect of birth weight, faculty versus resident operator, gestational age, abnormalities of first-stage labor, or several other factors. Prevention of perineal lacerations requires that the operator identify the patient at risk. Possible options for management of high-risk patients include use of mediolateral episiotomy or no episiotomy, use of vacuum extraction instead of forceps, and use of conduction anesthesia. (Am J Obstet Gynecol 1990;163:100-4.)

Key words: Perineal lacerations, forceps delivery, vacuum extraction delivery, episiotomy

Lacerations of the perineum are frequent complications of operative vaginal delivery and have substantial long-term morbidity. Lacerations that disrupt the anal sphincter capsule are associated with prolonged weakness of the sphincter muscle[1-5] and incontinence of flatus or stool in up to 40% of cases.[1-3] Dyspareunia and perineal pain may persist for years after third-degree lacerations[1, 2] and significant permanent disfigurement of the perineum often occurs.[1] Lacerations that violate the rectal mucosa carry added risks of infection, wound breakdown, and rectovaginal fistula. Many require secondary operative repair and cesarean section is often recommended for subsequent deliveries.[5]

A rational attempt to prevent lacerations must begin with a clear understanding of the factors that contribute to their occurrence. For spontaneous deliveries risk factors for perineal laceration include nulliparity,[6-9] midline episiotomy,[6, 8-11] macrosomia,[6, 9] delivery by residents,[6] delivery in lithotomy position,[12] and Asian race.[6] However, different factors may be relevant in operative deliveries. This article presents an analysis of factors associated with perineal lacerations in a large number of consecutive forceps and vacuum deliveries.

Material and methods

Moffitt Hospital is a teaching hospital of the University of California San Francisco. Since 1975 the hospital has maintained an ongoing computer data base that contains over 200 items of obstetric data on every delivery. Immediately after each delivery, data are coded onto forms by the delivering physician. The forms are reviewed by a professional chart abstractor before entry into the computer. Several logic checks and internal validity checks are performed during data entry to ensure a high degree of accuracy for each item entered.

Included in this study were all patients who had forceps or vacuum extraction delivery, vertex presentation, singleton gestation, gestational age >35 weeks, and delivery from January 1975 through July 1988. The one case coded as "high forceps" was excluded. Cases of failed forceps or vacuum extraction resulting in cesarean delivery were excluded. The study inclusion criteria were met in 2832 cases.

Lacerations were coded separately from episiotomy and included both spontaneous lacerations and extensions of episiotomy. Standard definitions for third- and fourth-degree lacerations were used: third-degree lacerations are those that disrupt the anal sphincter capsule but not the rectal mucosa; fourth-degree lacerations are those that involve the mucosa. First- and second-degree perineal lacerations, cervical and vaginal lacerations, and minor degrees of vulvar and periurethral trauma were not considered in this study.

The data base was recently revised to reflect the current classification of high, mid, low, and outlet forceps proposed by the American College of Obstetricians and

Gynecologists.[13] In more than 1000 cases, the material in the data base was inadequate to reclassify the pelvic level; the information was extracted by review of the original delivery notes and reentered into the data base.

Information was not available with regard to the type of forceps used (e.g., Simpson, Elliot). Although not coded in the data base, the Malmström vacuum cup was used in the majority of vacuum extractions. In rare cases when both forceps and vacuum were used, the instrument actually used to deliver the fetal head was coded. With regard to anesthesia, the coding in the data base did not allow distinction between local perineal infiltration and pudendal block.

An attending physician was typically present at delivery. Most deliveries were performed by a junior resident with the direct assistance of either a senior resident or attending physician. Some patients were treated in the faculty private practice and these were typically delivered of their infants by a faculty member. The data base contains three fields describing the levels and actual roles of the persons involved in delivery. For this study these fields were collapsed into a single code representing delivery by faculty or resident.

For the initial univariate analyses, several variables that might reasonably be associated with lacerations were explored. Statistical significance of relations was assessed by Yates-corrected χ^2 for categorical variables and by t test for continuous variables.

Multiple logistic regression was performed because of possible intercorrelations between the variables. All variables with significant ($p < 0.05$) or marginal ($p < 0.10$) univariate associations with perineal laceration were entered together in a main-effects model to determine the effect of each variable while simultaneously controlling for the effects of all the others. A logit model was fit to generate a maximum likelihood esti-

mate of the regression coefficient for each variable. Odds ratios and 95% confidence intervals were calculated from the coefficients and their standard errors. Variables with significant associations are those for which the confidence interval does not include an odds ratio of 1. The regression was performed with the PROBIT/MODEL = LOGIT procedure of SPSS-X.[14]

Results

Third-degree lacerations occurred in 555 deliveries (19.5%) and fourth-degree lacerations in 296 deliveries (10.5%), an overall laceration rate of 30.0%.

In the univariate exploration the factors shown in Table I were found to have an association with third- and fourth-degree laceration. The use of midline episiotomy was associated with nearly a threefold increase in risk for laceration. Nulliparous women had more than twice the risk of laceration compared with parous women. Other significant factors were delivery by a resident, presence of second-stage arrest, delivery from a low or mid station, use of local anesthesia, and use of forceps rather than vacuum extraction. There was a tendency for more lacerations in occipitoposterior deliveries and in women of Asian descent; however, these effects were of only marginal significance in the univariate analysis.

When patients who had lacerations were compared with those who did not, there was no difference in birth weight (3439 ± 462 vs 3423 ± 479 gm); gestational age (40.1 ± 1.5 vs 40.1 ± 1.6 weeks); the incidence of abnormalities of first-stage labor (prolonged latent phase, protraction, arrest, precipitous labor); the fraction of patients in whom labor was induced or augmented; the use of manual, forceps, or vacuum rotations; prenatal weight gain (15.6 ± 5.4 vs 15.3 ± 5.1 kg); the fraction of women who drank alcohol during pregnancy; the fraction who smoked or the number of cigarettes smoked per day. There were small differences in the length of the first stage of labor (687 ± 354 vs 652 ± 350 minutes; $p < 0.02$), in maternal age (26.6 ± 5.4 vs 27.1 ± 5.4 years; $p < 0.01$), and in prepregnancy weight (55.2 ± 10.1 vs 57.1 ± 10.7 kg; $p < 0.001$). However, these small differences were attributable to differences in parity between the groups and they were not considered further.

Before the multivariate analysis was performed all the variables in Table I were collapsed into dichotomous categories and coded as either present or absent. The ethnic category "other" was composed predominantly of Southeast Asians, Pacific Islanders, Indians, and Native Americans, thus these cases were coded as "Asian" together with Chinese, Filipino, and Japanese women. The anesthesia category "combination" was composed predominantly of combinations of local anesthesia with either epidural or saddle block, presumably because of inadequate conduction anesthesia. These cases were coded as "local" anesthesia. The few cases with no anesthesia or general anesthesia were excluded. Cases with missing values for any of the variables were excluded. After exclusions, 1978 cases were eligible for logistic regression analysis.

The results of the logistic regression analysis are summarized in Table II. With the exception of operator, all the factors considered in the model were associated with a statistically significant risk for perineal laceration. The adjusted odds ratio is a measure of the relative risk for laceration controlled simultaneously for the effects of the other factors. Clearly, midline episiotomy and nulliparity were the most important factors. The additional contributions of instrument, position, arrest of descent, anesthesia, station, and ethnic group were statistically significant but relatively small.

It was surprising that the status of the operator (faculty vs resident) did not have a significant bearing on the risk of laceration in the multivariate analysis. On examination of the covariances, it was found that the residents had a 50% higher incidence of perineal lacerations than the faculty because they had more patients in the high-risk Asian ethnic group (35% vs 22% of deliveries; $p < 0.001$) and because they used mediolateral episiotomy less often (25% vs 35% of deliveries; $p < 0.001$). When these factors were controlled, the laceration rates of residents and faculty were not significantly different.

Table III. Relationship between episiotomy and fourth-degree lacerations

Episiotomy	*No.*	*Fourth-degree lacerations*		*Relative risk*
		n	*%*	
Midline	1890	282	14.9	1
None	175	9	5.1	0.34*
Mediolateral	767	5	0.7	0.05†

*$p < 0.001$, compared with midline episiotomy, χ^2.
†$p < 0.001$, compared with no episiotomy, χ^2.

Finally, fourth-degree lacerations and their relation to episiotomy were examined separately (Table III). Clearly, midline episiotomy was associated with a high risk for fourth-degree laceration. The total number of lacerations after mediolateral episiotomy (five cases) and after no episiotomy (nine cases) was too small to support a multivariate analysis of the role of other risk factors.

Comment

The results show that several factors can be used to identify the patient at risk for perineal laceration with operative vaginal delivery and suggest potential strategies to reduce that risk.

Factors such as parity, second-stage arrest, station, and ethnic group are clearly beyond the control of the operator but should be known and considered before any operative intervention. Nulliparity is well known to be an important risk factor for perineal laceration in spontaneous deliveries.[6-9, 15] This effect is probably a result of the relative inelasticity of the nulliparous perineum. Inadequate time for perineal stretching probably explains the present observation that operative deliveries from stations higher than the outlet had increased risk for lacerations. Racial differences in perineal anatomy may also contribute to laceration. Green and Soo Hoo[6] found that Asian women had a high risk for perineal laceration in spontaneous deliveries and suggested that this may be caused by a relatively short perineal body in these women.

Of the factors under the operator's control, the choice of episiotomy is clearly the most important. In some operative deliveries the perineum is sufficiently distensible to allow delivery without episitiotomy, and this strategy may lower the risk for laceration.

The propensity of midline episiotomies to extend into the sphincter and the mucosa is well known.[10] A policy of routine mediolateral episiotomy for all operative deliveries would certainly result in fewer lacerations. However, mediolateral episiotomy is not entirely benign. It is widely believed that mediolateral episiotomies bleed more than midline episiotomies and heal with more complications. Dyspareunia is reported up to a year after mediolateral episiotomy.[16, 17] Although it is not clear whether mediolateral episiotomy is "worse" than a third- or fourth-degree laceration, the complications of laceration such as sphincter incontinence and fistula formation[1-5] are more likely to be permanent and potentially disabling than complications of mediolateral episiotomy. Thus we believe that selective use of mediolateral episiotomy is justified in a patient with several risk factors for laceration, especially nulliparity. If the patient has an epidural catheter in place during delivery, a dose of epidural narcotic may greatly alleviate the increased pain during the first postoperative day.

Vacuum extraction has been consistently found to result in less maternal soft tissue trauma than forceps delivery.[18-22] However, infants delivered with the vacuum extractor may have a higher incidence of cephalhematoma[18, 22-26] and hyperbilirubinemia that requires phototherapy.[18, 21, 26] It is debatable whether the small decreased risk to the mother justifies the routine use of vacuum extraction instead of forceps. The choice of instruments depends not only on a consideration of the risk of perineal laceration but also on the skills and training of the operator, the availability of the instruments, and other obstetric factors.

The effect of anesthesia on the risk for perineal laceration is incompletely understood. Studies of spontaneous deliveries have not detected a consistent effect of epidural anesthesia on the rate of lacerations.[6, 7, 15] Our results suggest either that local anesthesia increases the risk or that conduction anesthesia decreases the risk. It is possible that local infiltration somehow weakens the sphincter capsule and predisposes it to rupture during operative delivery. More likely is the possibility that conduction anesthesia relaxes the perineal musculature and provides a degree of protection. Regardless of the mechanism, these results suggest that epidural or saddle anesthesia should be considered before operative vaginal delivery if time and the fetal condition allow it.

The finding that birth weight and gestational age did not influence the risk of laceration was surprising and suggests that the instrument itself is the important factor influencing risk. The finding that deliveries performed by residents, after the other factors were con-

trolled, were no more likely to result in laceration than deliveries by faculty was also surprising and suggests that training and experience provide little protection to the perineum. Standard texts of operative obstetrics offer little guidance with regard to perineal management during forceps deliveries except to suggest that the blades be removed early and that a modified Ritgen maneuver be used to keep the fetal head flexed. Thompson[27] suggested that flexion could be maintained by active retraction of the anterior vaginal introitus but apparently found the technique unsatisfactory for forceps deliveries. Thacker and Banta[28] reviewed the diversity of opinions regarding where, when, and how pressure should be applied during delivery of the head and could not find a consensus.

It has been suggested that lithotomy position increases the propensity for laceration in spontaneous deliveries.[6, 12, 15] For operative delivery, the only reasonable alternative to lithotomy position is use of a birthing chair. However, randomized trials of birthing chairs for spontaneous deliveries have shown only minimally decreased rates of perineal laceration but substantially higher rates of postpartum hemorrhage.[29, 30]

The prevention of third- and fourth-degree perineal lacerations requires that the operator identify the patient at risk. Nulliparity, second-stage arrest, occipitoposterior position, nonoutlet station, and Asian race are significant risk factors. Mediolateral episiotomy, conduction anesthesia, and vacuum extraction might reasonably be considered for high-risk patients. Well-designed prospective trials are needed to determine the value of these interventions in prevention of perineal lacerations.

A comparison of tocolysis with nifedipine or ritodrine: Analysis of efficacy and maternal, fetal, and neonatal outcome

James E. Ferguson II, MD,[a] Donald C. Dyson, MD,[b] Thomas Schutz, BA,[a] and David K. Stevenson, MD[c]

Stanford and Santa Clara, California

Nifedipine, a dihydropyridone calcium entry blocker, has been used with increasing frequency in the treatment of preterm labor. We studied 66 patients in this prospective, randomized trial to evaluate the efficacy and maternal, fetal, and neonatal outcome associated with tocolysis with nifedipine or ritodrine. Delivery was delayed for 48 hours, 7 days, and until the thirty-sixth week of gestation in 84%, 70%, and 41%, respectively, of patients in the nifedipine group, compared with 72%, 63%, and 52% of patients in the ritodrine group (difference not significant). Maternal side effects were more common and more serious in the group of patients who received ritodrine compared with those who received nifedipine (18 of 38 versus 5 of 38, $p < 0.01$); however, fetal and neonatal outcome appeared to be similar when the groups were compared. On the basis of this study, it appears that tocolysis with either nifedipine or ritodrine is equally efficacious; however, maternal side effects are less common with nifedipine treatment. We conclude that nifedipine may have a role in the treatment of preterm labor but suggest further careful evaluation of this agent before it is considered for routine clinical use. (AM J OBSTET GYNECOL 1990;163:105-11.)

Key words: Nifedipine; ritodrine; labor, premature; tocolysis

β-Adrenergic receptor–blocking agents, specifically ritodrine, are the most commonly used drugs for the treatment of preterm labor.[1] Despite the widespread use of β-adrenergic tocolytic drugs for the past decade, a variety of serious and occasionally fatal side effects is continually encountered when patients are treated with these agents.[2, 3]

Nifedipine, a dihydropyridone calcium entry blocker, may represent an attractive therapeutic alternative to the β-adrenergic agents. This agent has well-known relaxing effects on the myometrium and has been used with increasing frequency in the pharmacologic treatment of preterm labor. The findings from several preliminary nonrandomized trials describing the clinical use of nifedipine in human beings suggest that this drug may be more efficacious than ritodrine with few apparent maternal or fetal side effects.[4, 5] However, previous studies may not have allowed for a rigorous comparative evaluation of this agent. Moreover, in some animal studies the administration of nifedipine has been associated with decreases in uterine blood flow and the occurrence of fetal hypoxia and acidosis.[6, 7]

Experience to date is limited with regard to the clinical use of nifedipine in humans, and questions still remain concerning the tocolytic effectiveness, the incidence of maternal and fetal/neonatal side effects, and the outcome of exposed neonates. To address these important issues, we designed this prospective, randomized study and compared tocolysis with nifedipine to tocolysis with ritodrine, currently the accepted standard and the only agent approved by the Food and Drug Administration.

Material and methods

Patients with preterm labor that occurred between 20 and 36 completed weeks of gestation who were seen in the Stanford University Hospital or Santa Clara Kaiser Hospital delivery rooms between July 1984 and August 1987 were eligible for enrollment into the study. Preterm labor was defined as regular uterine contractions at a frequency of eight or more per hour with a documented change in cervical dilatation or effacement before 36 completed weeks' gestational age. Informed consent, as approved by the Stanford University Committee for Protection of Human Subjects in Research and the Kaiser Permanente Human Subjects' Committee, was obtained from each patient. After preterm labor was diagnosed and written consent had been obtained, the assignment group was determined by

opening a sequentially numbered, sealed envelope, randomized by the use of a random number table with the patients stratified according to cervical dilatation (≤2 cm and >2 but ≤4 cm) and whether the patient had intact or ruptured membranes. Documented cervical change was recognized as a progressive increase in cervical dilatation, or percent effacement, or both that occurred between separate digital or speculum examinations by the same physician in patients with intact or ruptured membranes, respectively. Patients with the following maternal factors were excluded: known tocolytic exposure during the current pregnancy, diabetes, hyperthyroidism, cardiac disease, severe preeclampsia-eclampsia, abruptio placentae, chorioamnionitis, multiple gestation, hydramnios, and cervical dilatation >4 cm. Fetal distress, severe intrauterine growth retardation, dead fetus, or fetal anomaly incompatible with life constituted fetal factors for exclusion.

An intravenous infusion of 5% dextrose in lactated Ringer's solution at 100 ml/hr was administered to all patients after an initial 200 ml fluid bolus. In both study groups fluid intake was thus limited to 2400 ml/24 hr, and volume of total intake and urine output was recorded. Patients had no oral intake during the initial 24 hours of therapy except that sips of water were permitted to swallow oral medications. Maternal cardiovascular and metabolic parameters were determined at frequent intervals and the maternal and fetal-neonatal disposition of nifedipine was investigated; data from patients in each of these subgroups have recently been published.[8, 9] Before and at 12 hours of treatment, an electrocardiogram was obtained from each patient. Fetal heart rate and uterine activity were monitored continuously during the study. Cervical cultures for group B β-hemolytic streptococci and *Neisseria gonorrhoeae* were obtained. The use of amniocentesis and steroid administration followed our standard practice as previously described.[10]

Nifedipine tocolysis was initiated with a 10 mg capsule given sublingually. If uterine contractions persisted after 20 minutes, a similar dose was repeated at intervals of 20 minutes, up to a maximal total dose of 40 mg during the first hour of treatment. (Twenty-six patients received four sublingual doses, five received three doses, and two patients received two sublingual doses of nifedipine). If sublingual tocolysis stopped uterine activity, then oral therapy with 20 mg of nifedipine was initiated 6 hours after the last sublingual capsule. This dose was repeated at 4- to 6-hour intervals or, if needed to continue tocolysis, occasionally at more frequent intervals.

During treatment in the ritodrine group the infusion rate was begun at 50 μg/min and increased by 50 μg/min every 15 to 30 minutes in response to continued uterine activity until uterine contractions were inhibited, 350 μg/min was reached, or unacceptable side effects developed. Thereafter the infusion rate was decreased by 50 μg/min and was then maintained at that rate for 12 hours. (If labor recurred during this interval the above sequence was repeated.) After 12 hours the infusion rate was decreased by 50 μg/min every 2 hours until 100 μg/min was reached. Oral therapy (10 to 20 mg every 4 to 6 hours) was started 30 minutes before the discontinuation of intravenous ritodrine. (During oral therapy patients received 10 mg every 4 hours or 20 mg every 4 to 6 hours.)

Patients who had recurrent preterm labor while receiving oral nifedipine or ritodrine were treated sublingually or intravenously, respectively, with the same drug to which they had been randomized. If the uterine contractions stopped, they were again given their assigned oral tocolytic agent. In addition, although it was the intent to use only a single tocolytic agent in each patient and to allow delivery if uterine contractions with progressive cervical dilatation persisted or if a maternal side effect required the discontinuation of the tocolytic agent, in 10 cases physicians caring for patients who were failing with one treatment agent switched them to the other in an attempt to prevent delivery. Because these "crossover" cases allowed us to compare whether patients might respond to the alternate tocolytic agent, they too are described.

When patients had been stable while receiving oral tocolytics for 12 to 24 hours they were transferred from the labor and delivery unit to an antepartum ward, and were then discharged home after 1 to 2 additional days of hospitalization, during which activities consisted of bed rest with bathroom privileges. As outpatients they were seen at weekly intervals and had frequent evaluation of the cervical state and reenforcement of the educational instructions concerning the signs and symptoms of preterm labor. Ambulatory home uterine contraction monitoring was not used.

In both the nifedipine and ritodrine treatment groups, our goals for tocolysis were to delay delivery for 48 hours in patients with ruptured membranes, and through 36 completed weeks of gestation in patients in whom the membranes were intact. Therapy was considered successful when, in each respective group, delivery was delayed for these intervals. In patients with intact membranes we also evaluated the ability of these drugs to postpone delivery for 1 week. Treatment failure was said to exist if, despite maximal dosages of nifedipine or ritodrine, uterine quiescence could not be achieved and delivery occurred, or if because of continued uterine contractions and cervical dilatation, a patient was switched to the alternative therapy before the described intervals of tocolysis had been attained. If a patient had a significant maternal side effect that the attending obstetrician judged to necessitate discontinuation of the medication or change to the alternative

Table II. Delay in delivery*

	48 hr		*7 days*		*36 wk*	
Tocolytic agent	*No.*	*%*	*No.*	*%*	*No.*	*%*
Nifedipine	27/32	84	16/23	70	9/22	41
Ritodrine	23/32	72	17/27	63	14/27	52

*No intergroup comparisons were statistically significant by χ^2 analysis.

therapy, or if spontaneous rupture of membranes developed, a treatment failure was said to have occurred.

Information concerning side effects and their management was carefully recorded about each patient by the physician or nurse caring for the patient. Treatment of side effects was individualized. In most instances expectant management or symptomatic treatment was sufficient. A reduction in the amount or interval of administration of the therapeutic agent was usually helpful in treating patients who complained of nausea and vomiting or chest pain. In some patients, however, persistent and worrisome side effects prompted the treating physician to discontinue tocolytic therapy.

Statistical analysis was performed with the Student's t test, χ^2 analysis with Yate's correction, one-way analysis of variance, or Fisher's exact test where appropriate to determine significance ($p < 0.05$).

Results

Sixty-six patients were enrolled in the study; 33 were randomized to nifedipine treatment and 33 to ritodrine. It was unknown at the time of randomization and initial hospital care that two patients in each group had received a single subcutaneous 0.25 mg dose of terbutaline before transfer to the study institutions. They are included in this evaluation of tocolytic success and maternal and fetal/neonatal outcome.

Patients in the two treatment groups were first compared for various factors that could contribute to success of tocolysis and maternal or fetal/neonatal outcome. Table I shows that there was no significant difference in maternal age, parity, gestational age, cervical dilatation or effacement, use of steroids, or incidence of ruptured membranes when the two groups were compared.

The overall duration of successful therapy can be noted in Table II. Use of nifedipine delayed delivery for 48 hours in 84% (27/32) of the patients. (One patient in the nifedipine treatment group who had intact membranes and whose labor was successfully arrested for 24 hours requested withdrawal from the study and was treated with terbutaline. Terbutaline tocolysis failed and she was delivered of a previable infant.) Of note, tocolysis was successful in six of the eight patients with spontaneous rupture of membranes. As noted in the Material and methods section, in patients with spontaneous rupture of membranes tocolysis was not attempted beyond 48 hours, and after the cessation of tocolytic therapy delivery ensued in all patients within 7 days. Two other patients were withdrawn from further analysis of efficacy in the nifedipine group. In one patient with intact membranes and oligohydramnios, tocolysis was used only for 48 hours to administer steroids and was then discontinued to allow delivery. The second patient was withdrawn from further analysis of efficacy because after 36 days of successful tocolysis, she failed to refill her prescription and came to the hospital 1 day later in advanced labor. Therefore tocolysis had been attempted in 23 patients at 7 days and in 22 patients by 36 weeks. Delivery was delayed in 16 (70%) of 23 patients at 7 days and beyond 36 weeks in 9 (41%) of the 22 patients. In the group of patients randomized to receive ritodrine, tocolysis was success-

Table III. Treatment failures and the alternate agent to delay delivery an additional 48 hours

Initial agent	*Alternate agent used*		*No alternate agent*	
	No.	*Delay ≥48 hr*	*No.*	*Delayed ≥48 hr*

†Some patients had more than one side effect. ($p<0.01$, Fisher's exact test of probability).

ful for 48 hours in 72% (23/32). (A single patient with spontaneous rupture of membranes in the ritodrine group was withdrawn from the study because she was found to have a mature lecithin/sphingomyelin ratio and tocolysis was discontinued and delivery subsequently occurred.) Of the five remaining patients with spontaneous rupture of membranes in the ritodrine group, tocolysis was successful in two, then the medication was discontinued and delivery occurred within 1 week. Twenty-seven patients remained in the ritodrine treatment group; delivery was delayed for at least 1 week in 17 (63%) and until at least 36 weeks in 52% (14/27). There were no statistically significant differences between the two treatment groups when compared at the three durations of tocolysis.

Treatment failures occurred in 15 patients in the nifedipine treatment group (Table III). In five instances crossover therapy with intravenous and then oral ritodrine was attempted by the attending physician; tocolysis was accomplished in three cases with a further prolongation of pregnancy of 16, 35, and 60 days. Ritodrine tocolysis was not successful in the other two cases. In the remaining 10 cases no alternate agent was used and delivery occurred in all within 12 hours. In the ritodrine group there were 16 treatment failures. Crossover treatment with sublingual and then oral nifedipine was attempted in five patients, and delivery was delayed in three patients for 50, 68, and 84 days. When no alternate agent was used, delivery occurred in the remaining 11 patients within 12 hours. Overall, patients in whom crossover therapy with the alternate agent was attempted had a significantly greater chance of delaying delivery beyond 48 hours ($p < 0.001$) when compared with patients in whom the alternate agent was not used.

The maternal side effects in the two treatment groups are compared in Table IV. For the purpose of this enumeration, the five "crossover" patients from each group have been included in both their original group and their alternate drug group. Side effects were tabulated according to the drug the patient was taking when they occurred. Side effects occurred more commonly in the ritodrine group ($p < 0.01$). In the ritodrine treatment group chest pain and nausea or vomiting were the most common side effects. Although in most instances a reduction in the infusion rate of ritodrine and symptomatic treatment alleviated these complaints, in three patients it was necessary to discontinue the infusion. One of these three patients had multifocal premature ventricular contractions; the second had supraventricular tachycardia successfully treated with intravenous verapamil after failure of carotid sinus massage and the Valsalva maneuver; and in the third patient, despite a normal electrocardiogrm and reduced infusion rate, the persistent and oppressive chest pain was clinically judged to require discontinuation. In the nifedipine group headache and flushing were the most common complaints. Chest pain and pressure associated with pyrosis was encountered in one patient in the nifedipine group and was successfully treated with ant-

acids and elevation of the head of the patient's bed. Of the 10 patients who sequentially received both tocolytic agents, two had side effects. One patient who had headaches while receiving nifedipine also had headaches while receiving ritodrine but in addition had nausea and vomiting. In an additional patient who was receiving intravenous ritodrine at a gestational age of 26 weeks, recurrent uterine contractions with progressive cervical dilatation occurred. Pulmonary edema was also diagnosed. She was treated with morphine sulfate, oxygen, and diuretics and switched to nifedipine; however, continued attempts at tocolysis were unsucessful.

Outcome data for the neonates exposed in utero to only nifedipine and ritodrine, as well as those sequentially exposed to both agents, are detailed in Table V. There were no significant differences when intergroup comparisons were performed on outcome parameters. There was a single fetal demise in the study. In this pregnancy tocolysis was initially accomplishd with nifedipine, but failure occurred after 4 days and intravenous and then oral ritodrine tocolysis was attempted and successful. Because of ultrasonographically suspected fetal anomalies at the time of initial evaluation, amniotcentesis had been performed for cytogenetic studies. Sixteen days later the patient presented after failure of ritodrine therapy with fetal demise; the then completed cytogenetic studies revealed trisomy 13. Two neonatal deaths occurred in the nifedipine group. In one case the patient, as described above, requested withdrawal from the study after 24 hours of successful tocolysis with nifedipine and was subsequently treated with terbutaline and within 15 hours was delivered of a 22-week gestation with Apgar scores of 1 at 1 minute and 1 at 5 minutes that died in the first hour of life. The second neonate, a male delivered at 28½ weeks, had Apgar scores of 2 and 6 at 1 and 5 minutes, respectively, died at 11 days of age. The neonatal course was complicated by severe respiratory distress syndrome and the rapid development of pulmonary interstitial emphysema. Obstetric complications, in addition to continued uterine contractions, included a partial placental previa with active bleeding, bulging chorioamniotic membranes with a funic presentation, and the need for an urgent cesarean section. The infant's cord pH was 7.38 at the time of delivery. There was no evidence of hypovolemia or of any possible cardiovascular effects of nifedipine. The neonatal evaluation concluded the cause of death was unrelated to nifedipine administration and attributed it to severe respiratory distress syndrome and pulmonary interstitial emphysema, with hypoxemia refractory to mechanical ventilation and pharmacologic cardiopulmonary intensive care. The two neonates in the group exposed to both drugs, who had respiratory distress syndrome and required ventilator treatment at 2 and 4 weeks after delivery, were each delivered after ritodrine therapy and subsequent attempted tocolysis with nifedipine had failed. The neonates with intraventricular hemorrhage all had grade I hemorrhages.

Comment

We have demonstrated that nifedipine appears to be a comparable but not superior tocolytic agent when compared with ritodrine hydrochloride. Two previous studies have reported on the tocolytic efficacy of nifedipine when used as a primary agent. Ulmsten[4] studied 28 patients in preterm labor (eight of whom were also hypertensive). All patients had previously uncomplicated singleton gestations between 27 and 33 weeks, two or more uterine contractions in 10 minutes, and an effaced cervix that was not dilated >4 cm. Treatment was initiated with 30 mg of nifedipine orally, followed by 20 mg orally three times a day for 3 days, then twice a day thereafter. Tocolysis was reported to

be successful for 72 hours in 80% of the patients. In a second study by Read and Wellby,[5] patients were assigned in a nonrandom format to receive nifedipine, ritodrine, or no tocolytic treatment. Patients were included for the treatment of preterm labor if there was a contraction frequency of at least once every 10 minutes, the membranes were intact, and the cervix was not dilated beyond 4 cm. Nifedipine was administered as a single course of 30 mg orally followed by 20 mg orally at 8-hour intervals for 3 days. The authors reported a significantly greater percentage of "postponement of delivery" (delay beyond 48 to 72 hours) when patients treated with nifedipine (15 of 20, 75%) were compared with patients treated with ritodrine (9/20, 45%) or untreated patients (7/20, 35%). In these two studies there was no description of success at delaying delivery for longer intervals. Our study design was somewhat different from those used in the previously mentioned reports in that our definition of preterm labor was more stringent, we included patients with spontaneous rupture of membranes, and because initial tocolysis for patients in the nifedipine group used incremental doses of sublingaul nifedipine to obtain more rapid serum concentrations.[9] In addition, we chose to evaluate the shortest interval of success of tocolysis as 48 hours instead of 72 hours because this is the amount of time we attempt to gain for the fetus in utero to enhance fetal lung maturity with glucocorticoid administration. Despite the differences in study designs, the combined success we report in delaying delivery for both 48 hours and 1 week after the initiation of therapy is very similar to the rate of tocolytic success and "postponement of delivery" reported by Ulmsten[4] and Read and Wellby,[5] respectively. We cannot confirm the findings of Read and Wellby[5] with regard to the superiority of nifedipine when compared with ritodrine. In our study no significant differences were demonstrated between treatment groups when success of tocolysis was compared for any of the three intervals at which delays in delivery were evaluated. Additionally, the proportion of patients in this report who achieved 36 completed weeks' gestational age when either nifedipine or ritodrine was used is similar to the proportion of patients recently reported by Wilkens et al.[11] who were delivered after 37 weeks' gestation after aggressive treatment with ritodrine, magnesium sulfate, or both.

Our findings also demonstrate that nifedipine treatment may be useful to achieve delay of delivery in patients in whom a treatment failure has occurred with ritodrine and that the converse is true as well. Although the patients in whom crossover therapy was attempted were not randomly selected, it appears that they had a significantly greater chance of having gestation prolonged an additional 48 hours when compared with patients who received no further treatment. Preterm labor is probably a syndrome of disorders with different causes and associated pertubations of the mechanisms responsible for regulating uterine contractility. Although the regulation of uterine contractility is complex and incompletely understood, it is believed that β-adrenergic and calcium channel-blocking agents each act through a different cellular mechanism to achieve uterine quiescence.[12] Consequently, it should not be surprising that both nifedipine and ritodrine may, because of their different sites of tocolytic action, be effective when used after a treatment failure of the other agent.

When a tocolytic agent is chosen, an important consideration beyond efficacy is the possible occurrence of maternal or fetal side effects. Our findings document a greater incidence and severity of maternal side effects in patients in the ritodrine group when compared with patients in the nifedipine group. The side effects that occurred with ritodrine usage were similar in variety and type to those previously reported.[2, 11] When chest pain occurred, despite the fact that a reduction in the infusion rate of ritodrine usually ameliorated this symptom, in three patients discontinuation of the infusion was necessitated. We[13] and others[2, 3, 11] have previously reported that there appears to be a small proportion of patients who do not tolerate β-adrenergic therapy because of the occurrence of cardiac symptomatology. Nausea or vomiting was the next most frequently encountered side effect in our study. Caritis et al.[14] reported the same incidence of this side effect, whereas Wilkens et al.[11] reported this finding less frequently. We encountered few side effects associated with nifedipine usage. The proportion of patients who complained of headaches was similar to that reported by Ulmsten[4]; however, we encountered less flushing, perhaps because of a difference in treatment regimens. Read and Wellby[5] noted that troublesome side effects occurred much more commonly in the patients receiving ritodrine when compared with those receiving nifedipine or no therapy. Neither Ulmsten[4] nor Read and Wellby[5] reported any serious maternal side effects in patients treated with nifedipine.

None of the variables of perinatal outcome that we assessed appeared to be affected differently by either treatment regimen or when the drugs were used sequentially. Ulmsten[4] reported two neonates with Apgar scores less than 7, encountered no perinatal deaths, and found appropriate birth weights in the neonates. Read and Wellby[5] also reported similar Apgar scores in the nifedipine and ritodrine groups and no perinatal deaths. In a recent study by Adam et al. (Adam K, Kirshon B, Lee W, Spillman T, Johnson D, Mauer MB, Cotton DB. Acid-base balance in the human fetus during nifedipine therapy [Abstract 209]. In: Proceedings of the Ninth Annual Meeting of the Society of Perinatal Obstetricians, New Orleans, Louisiana, February 2-4, 1989) eight patients in preterm labor were treated with 30 mg of nifedipine orally, followed in 4 hours by an additional 20 mg oral dose. Six hours after the initial

dose of nifedipine, the maternal mean arterial pressure was compared with baseline, and umbilical cord blood sampling was performed to evaluate fetal acid-base status. These investigators demonstrated that the maternal mean arterial pressure did not change and there was no evidence of fetal acidosis or hypoxia.

Despite the favorable fetal-neonatal outcomes to date with use of nifedipine in human gestations, the animal data documenting maternal and fetal hemodynamic and associated cardiorespiratory responses have reported variable effects in different species; some of the findings provide reason for possible concern and continued careful surveillance. Veille et al.[15] studied the effects of bolus infusion of 5 to 45 μg/kg of nifedipine on uterine blood flow and maternal mean arterial pressure in pygmy goats; there was no significant change in uterine blood flow and only an immediate and transient fall in mean arterial pressure. Conversely, Ducsay et al.[6] and Harake et al.[7] investigated the effects of nifedipine administration in pregnant rhesus monkeys and ewes, respectively, and reported decreases in maternal mean arterial pressure and uterine blood flow with associated fetal hypoxemia and acidosis. Harake et al.[7] believe that decreases in uterine blood flow occur only with significant decreases in maternal mean arterial pressure and that fetal hypoxemia, when present, is most likely related to a fall in uterine blood flow. It is thus possible that adverse fetal hemodynamic and cardiorespiratory effects have not been demonstrated in human pregnancies when nifedipine is used because only minimal changes in maternal hemodynamics occur.[4, 5, 8]

We have demonstrated that the tocolytic efficacy of nifedipine appears to be comparable with but not superior to that associated with the use of ritodrine. We have also provided the initial documentation that nifedipine can be used to delay delivery in patients with spontaneous rupture of the membranes. In addition, nifedipine may successfully delay delivery if ritodrine tocolysis fails, and the converse was also found. Maternal side effects occurred less frequently when nifedipine was used. The perinatal outcome indicated no differences between treatment groups; however, caution must be exercised in the interpretation of this information. Despite over 3 years of patient enrollment, our study consisted of a relatively small sample size and therefore the possibility of a type II or beta error exists. Although the power of our study was less than the often accepted 80%, assuming the outcome variable proportions remain unchanged, a study population of more than 1000 patients would be required to be certain the null hypothesis is not accepted when incorrect.

On the basis of this work and previous investigations by us,[8, 16] Adams et al., and others,[4, 5] it appears that nifedipine may have a role in the therapeutic armamentarium for the treatment of preterm labor. It may be especially useful if it is necessary to minimize maternal side effects and avoid significant alterations in cardiovascular and metabolic parameters or if a patient has a treatment failure with a β-adrenergic agent. Because knowledge concerning the use of nifedipine as a tocolytic agent in human pregnancy and its possible maternal and fetal-neonatal side effects is still nascent, we believe nifedipine should only be used after obtaining informed patient consent, preferably as part of a prospective, randomized investigative trial.

We thank Barbara J. Burkett, PhD, for her kind assistance with the statistical evaluation.

Discrepancy in the diagnoses of hydatidiform mole by macroscopic and microscopic findings and the deoxyribonucleic acid fingerprint method

Hiroaki Takahashi, MD,[a] Koji Kanazawa, MD,[a] Toshihiko Ikarashi, MD,[b] Norihito Sudo, MD,[b] and Kenichi Tanaka, MD[a]

Niigata, Niigata, Japan

Ten cases of hydatidiform mole were analyzed by the deoxyribonucleic acid fingerprint method. Deoxyribonucleic acid samples were prepared from hydatidiform mole tissue of hydatidiform mole and maternal and paternal blood. A case of partial hydatidiform mole diagnosed by histologic findings was revealed to be complete hydatidiform mole by deoxyribonucleic acid fingerprinting. (AM J OBSTET GYNECOL 1990;163:112-3.)

Key words: Hydatidiform mole, DNA fingerprint, androgenesis

Gestational trophoblastic disease has been classified by international committees such as the Union Internationale Contre le Cancer, World Health Organization, and the International Federation of Gynecology and Obstetrics. The classification of noninvasive hydatidiform mole included complete hydatidiform mole and partial hydatidiform mole. These have been macroscopically diagnosed. However, it has been recommended that histologic classification should be carried out. The deoxyribonucleic acid (DNA) fingerprint method is available for personal identification and for determination of true parenthood.[1] Inasmuch as complete hydatidiform moles are of androgenetic origin but partial hydatidiform moles are not and are a result of a chromosomal anomaly of mainly a triploid karyotype, the DNA fingerprint method should be useful in distinguishing partial hydatidiform moles from complete hydatidiform moles. It is important to accurately diagnose complete hydatidiform moles and partial hydatidiform moles because of the incidence of persistent trophoblastic disease.

We have studied 10 cases of hydatidiform mole including three cases of partial hydatidiform mole. DNA samples were prepared from the molar tissue and parental blood, and DNA fingerprinting was performed. Hydatidiform moles were analyzed by DNA fingerprinting and the diagnoses were compared with macroscopic and microscopic diagnoses. A case of partial hydatidiform mole diagnosed by histologic findings was revealed to be complete hydatidiform mole by DNA fingerprinting.

Case report

A 28-year-old gravida 1, para 1 woman underwent curettage at 12 weeks' gestation under the diagnosis of hydatidiform mole. The diagnosis was partial hydatidiform mole macroscopically and microscopically (Fig. 1). The hydropic tissue was separated from nonhydropic tissue and collected, and the DNA fingerprint was performed (lane 1, father; lane 2, mother; lane 3, hydropic tissue; and lane 4, nonhydropic tissue in Fig. 2). The bands of the DNA fingerprint of hydropic tissue were almost the same as those of the paternal gene, but not of parental origin. Because the urinary human chorionic gonadotropin titer did not go down in 1 month after evacuation of the mole and lung metastasis was identified by roentgenogram of the chest, the patient was treated by three courses of methotrexate (one course, methotrexate 10 mg/day × 5 days). The urinary human chorionic gonadotropin level went down to the leuteinizing hormone level 2 months after treatment.

Comment

The case was thought to be partial hydatidiform mole by macroscopic and microscopic methods. However, it was indicated by DNA fingerprinting to be complete hydatidiform mole. It might be a dizygotic conception with a complete hydatidiform mole and an abortion. Such a twin pregnancy was reported by chromosomal analysis.[2] We thought that the case should be dealt with

as complete hydatidiform mole. In fact, it was found to be persistent trophoblastic disease and was treated by chemotherapy.

The merits of DNA fingerprinting are that materials can be stored easily and the experiments can be made at any time, which is not possible by chromosomal analysis. Also, DNA fingerprinting can be available for the classification of complete hydatidiform mole and partial hydatidiform mole.

Autogenic masculinization

Margaret R. Punch, MD, and Rudi Ansbacher, MD, MS
Ann Arbor, Michigan

We present a case in which self-treatment of lichen sclerosus with large doses of topical testosterone resulted in marked masculinization and may have caused secondary amenorrhea. These changes have not previously been reported as side effects of topical testosterone use. (AM J OBSTET GYNECOL 1990;163:114-6.)

Key words: Lichen sclerosus, testosterone therapy

Lichen sclerosus is a vulvar dystrophy associated with pruritus and diffuse whitish change in the vulvar skin. The skin may appear thin and atrophied or contain fissures. Histologically, the epithelium is thinned with loss of rete ridges and may be noted to have hyperkeratosis at the surface level. The standard treatment approach is topical application of 2% testosterone propionate in petrolatum ointment. The amount needed for each application to the vulvar tissues usually represents 8 to 10 mg of testosterone. The usual regimen of therapy is an application twice a day for the initial period of 6 weeks or until symptoms of pruritus resolve. The dosage is tapered, if the drug is effective, to a maintenance application as infrequently as twice a week. Effectiveness is reported to be high and side effects minimal. In this case report the patient was using up to 60 mg of topical testosterone on a daily basis for a prolonged period of time.

Case report

The patient, a 27-year-old nulligravid woman, gave a history of having lichen sclerosus et atrophicus on the basis of a biopsy done more than 1 year previously at another institution. She had been placed on a regimen of topical testosterone therapy. Laboratory values from March 1988 at the University of Michigan Medical Center included follicle-stimulating hormone 5.6 MIU/ml, luteinizing hormone 2.9 mIU/ml, and estradiol 38 pg/ml. She was advised to continue topical testosterone twice weekly.

She presented to the Infertility and Endocrinology Clinic in the Department of Obstetrics and Gynecology on June 13, 1988, for evaluation of amenorrhea and lichen sclerosus. A complete history was obtained and a physical examination was done at that time.

This 27-year-old nulligravid woman underwent uneventful menarche at age 12. She had monthly cycles with 3 to 4 days of menstrual flow. She used a variety of oral contraceptives from age 18 to age 26. She discontinued these in June 1987. She noted two spontaneous menses after discontinuing the oral contraceptives but had her last normal menstrual period in September 1987. She noted 2 days of spotting in January 1988 and 3 days of spotting just before her clinic visit in June 1988.

The patient was a graduate student in biology and had been mixing her own testosterone ointment. Although she had been placed on a standard dosage regimen more than 1 year before she was seen, she had been self-treating with this homemade testosterone ointment, topically applying an estimated dosage of 7.5 mg seven to eight times a day for at least 8 months. She complained of painful clitoral adhesions. She noted hot flashes and night sweats for 1 year but denied acne, hirsutism, temporal balding, breast atrophy, or weight changes. Deepening of her voice had occurred since she had been using the testosterone. She had recently begun using topical vitamin A and tapering the testosterone usage. The patient was not sexually active.

Physical examination revealed height 60½ inches, weight 93 pounds, and blood pressure 118/80 mm Hg. There was no thyromegaly. Her voice was deep. She had no facial or chest hair. The breast examination revealed small breasts with no masses, tenderness, or galactorrhea. There was no organomegaly on abdominal examination. On pelvic examination there was increased hair growth on the inner legs and upper thighs. The clitoris was enlarged, measuring 2 cm (previous size had not been documented). Some periclitoral adhesions were present along with minimal hypertrophic changes of the vulvar skin. The introitus was nulliparous, and the cervix was without lesions. The uterus was small and retroverted, and both ovaries were palpable and not enlarged.

The patient had begun taking basal body temperature 24 days before she was seen in June 1988. She had a biphasic chart with a 6-day temperature elevation

6/1/20100

before the onset of vaginal spotting, which was 3 days before she was seen in the infertility Endocrinology Clinic.

The impression at the time of the visit in June 1988 was that the patient had secondary amenorrhea and lichen sclerosus. Because of the virilization we suspected that she might have a component of polycystic ovarian disease. She was advised to discontinue the topical testosterone. Blood studies obtained were as follows: testosterone 11.15 ng/ml (normal 0.24 to 0.66 ng/ml), thyroid-stimulating hormone 2.1 (normal <7.0 IU/L), prolactin 7.7 ng/ml (normal 2 to 22 ng/ml), dehydroepiandroestrone sulfate 4145 ng/ml (normal 820 to 3800 ng/ml, female adult). A Papanicolaou smear was negative.

When seen again on July 13, 1988, the patient reported that she had discontinued the testosterone applications on June 15. She had 2 days of spotting on July 6 and 7. Results at repeat pelvic examination were unchanged. A repeat testosterone level was obtained on Aug. 15, 1988. It had fallen from 11.15 to 0.53 ng/ml, which was within the normal range for a female adult. When seen on Aug. 17, 1988, she was asymptomatic for lichen sclerosus and was still applying vitamin A cream topically to the vulva. She reported a normal menstrual period on July 28, 1988, lasting 3 days. Her voice was still deep. One year later she reports continued regular menstrual cycling.

Comment

Androgenic agents have many uses in modern medical therapeutics. These uses range from hormonal replacement in male patients with some hypogonadal states to stimulation of erythropoiesis in patients with aplastic anemia or chronic renal failure. Androgens also are used in the treatment of women with breast cancer.

The topical use of testosterone to treat vulvar dystrophy dates back more than 40 years. In 1945 Cinberg reported on the therapy of postmenopausal patients with vulvar pruritus. He advised the use of a bland ointment containing petrolatum alba, starch, and zinc oxide. In those patients with severely atrophic vulvar tissues he used androgenic ointments, specifically, an ointment containing 2 mg of testosterone propionate to each gram of ointment.

Richardson and Williams reported on 57 patients with vulvar dystrophy treated with topical testosterone for from 1 to 15 years. Results were classified as excellent or satisfactory in 50 patients as long as maintenance treatment was continued. Noted side effects included increased libido, increase in pubic and genitourinary hair, and a few patients with increased facial hair. Increased clitoral size also was noted but seemed to diminish after 3 to 4 years of therapy. In patients with relief of pruritus, none were willing to stop the treatment because of the side effects. Of these 57 patients, 46 were felt to have what is currently considered lichen sclerosus or a mixed dystrophy. All but five of these were improved by the topical testosterone therapy.

Friedrich[1] in 1976 reviewed the literature on lichen sclerosus and found that 130 of 137 cases of lichen sclerosus or mixed dystrophy showed improvement with topical testosterone therapy. Side effects were again thought to be minimal. Thus the regimen described by Richardson and Williams has become and remains the standard of care. Their regimen involves the application of 2% testosterone propionate ointment two to three times a day for 6 weeks or until relief of symptoms. Applications are then tapered to twice weekly. The usual application is about 10 mg of testosterone. Corticosteroids may be used initially to help reduce inflammation, if present.

There are few data in the literature on the effect of topical testosterone on serum steroid levels. In 1971 Zelle[2] reported on 15 patients treated with Richardson and Williams' treatment regimen. Nine of these patients had lichen sclerosus et atrophicus and six had hyperplastic dystrophy. Five patients had plasma androgen levels determined during active therapy and five others had 17-ketosteroid levels measured. No abnormal levels were reported. Four patients noted moderate clitoral hypertrophy and increased libido. Two patients noted only increased libido. It is not known if the patients who experienced the side effects were in the groups who had blood studies done.

In 1984, Friedrich and Kalra[3] reported on 30 women with untreated, biopsy-proved lichen sclerosus who had sex steroid hormone levels determined before initiation of topical testosterone therapy. Ten of these women had repeat levels measured at varying times in the treatment, which showed an increase in total testosterone from an average of 0.225 to 0.875 ng/ml. Dihydrotestosterone levels increased from an average of 0.07 to 0.28 ng/ml. Of the 10 patients with two hormone level determinations only one noted side effects, and those were confined to pubic hirsutism and slight facial acne. Two of the 10 noted no response to therapy despite a documented increase in serum androgen levels indicating some systemic absorption of the topical medical.

Although the diagnosis of polycystic ovarian disease was initially considered, review of the laboratory values led to the impression that she had stigmas of polycystic ovarian disease caused by exogenous androgen. Amenorrhea is one of the clinical findings in patients who have virilization caused by polycystic ovaries, some ovarian neoplasms, and exogenous androgen. The patient in this case report most likely had secondary amenorrhea in association with the dose of topical testosterone she was absorbing. The cause of the amenorrhea may have been chronic anovulation, as well as a com-

ponent of endometrial atrophy resulting from the antiestrogenic effect of testosterone. An endometrial biopsy was not done. The basal body temperature chart was biphasic at the time of presentation, and this may have reflected a spontaneous ovulation as she had already begun to taper her testosterone usage.

This case report demonstrates the effect of high-dose topical testosterone therapy. The dosages estimated to be applied to the vulvar tissues of this patient were twice the amount recommended in the acute phase of treatment and at least 15 times the usual maintenance dosage. These are dosages that have never been advocated in the literature. The resultant masculinization, as well as the markedly elevated serum testosterone level, points to the effectiveness of the vulvar skin in absorbing topical testosterone into the systemic system. These menstrual changes and the deepened voice have not been reported as side effects in previous studies regarding the topical use of testosterone by women. Discontinuation of the topical testosterone resulted in the resumption of spontaneous menstrual bleeding. The testosterone level returned to normal within 2 months. Lichen sclerosus was stable in the short-term follow-up available. Some low-dose maintenance therapy may be necessary for her to remain symptom-free. Voice changes are irreversible.

In summary, this case report stresses the importance of proper dosing with topical testosterone. Usual dosages have been associated with minimal side effects; however, excessive dosing may result in impressive masculinization and secondary amenorrhea because of the systemic absorption of the topically applied ointment.

Vulvar ulcer of unknown etiology in a human immunodeficiency virus–infected woman: Response to treatment with zidovudine

Jean Marie Covino, RPA, and William M. McCormack, MD
Brooklyn, New York

We report a woman who presented with an intractable vulvar ulcer of unknown etiology. Human immunodeficiency virus antibodies and a depressed CD4 lymphocyte count were the only remarkable findings. There was no evidence of syphilis, chancroid, or herpes simplex virus infection. The ulcer healed in association with treatment with zidovudine. (Am J Obstet Gynecol 1990;163:116-8.)

Key words: Vulvar ulcer, human immunodeficiency virus, zidovudine

This report describes a woman who had a refractory vulvar ulcer of unknown etiology when she was first seen. There was laboratory evidence of infection with human immunodeficiency virus (HIV), and treatment with zidovudine was associated with healing of the ulcer.

Case report

A 34-year-old, white woman was first seen in August 1986 because of genital warts. She was born in Brooklyn, New York, and was a lifelong resident. She was employed as a data-entry clerk. She lived with her three

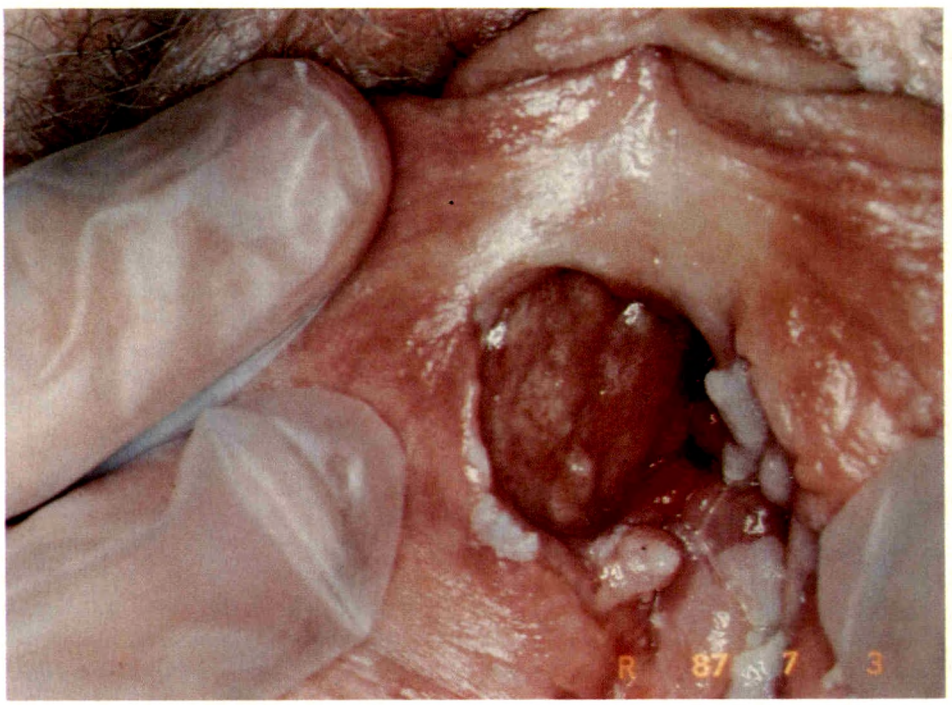

Fig. 1. Right vestibular ulcer before treatment with zidovudine (March 1987).

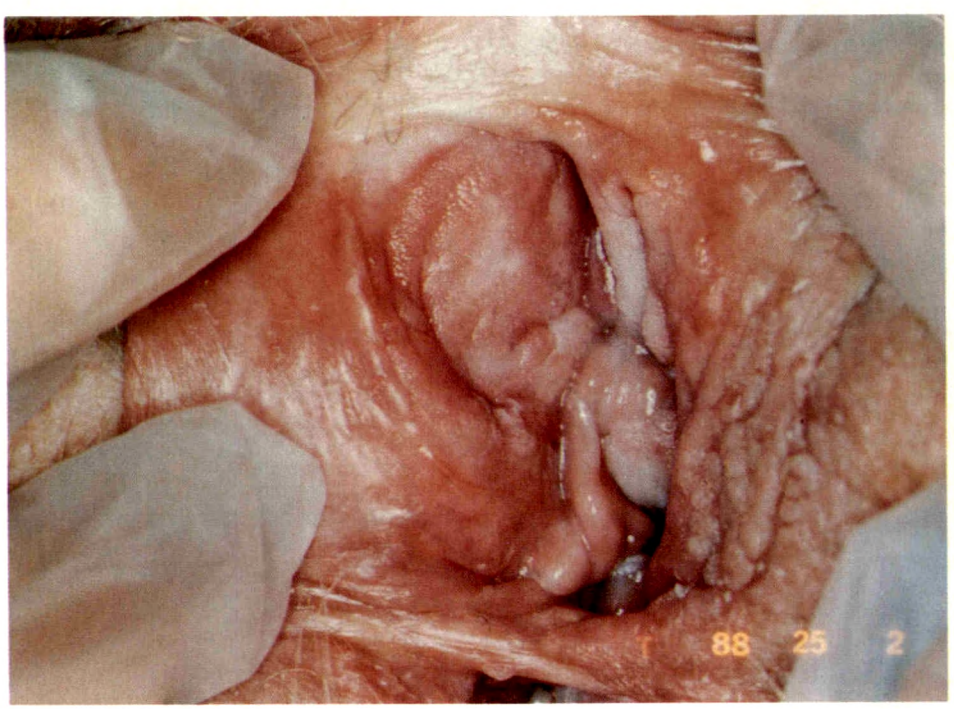

Fig. 2. Right vestibular ulcer after treatment. The ulcer has reepithelialized (February 1988).

daughters, aged 10 to 15. She had been separated from her husband for 10 years. Since the separation she had had six male sexual partners. Although the patient gave no history of illicit drug use, her husband had used drugs and died of "pneumonia" in early 1987. She had received a blood transfusion in Brooklyn, New York, in 1980 when she was treated for an ectopic pregnancy.

The genital warts were ablated with use of a laser. Subsequently she was noted to have recurrent condylomas and a painful right vestibular ulcer. She also reported recurrent painful oral ulcers that healed spontaneously. The vestibular ulcer enlarged despite treatment with erythromycin, acyclovir, ceftriaxone, and doxycycline. By March 1987 the ulcer had increased to 4 cm in size (Fig. 1). There were aphthous ulcers of the inner aspect of the left upper lip and of the right tonsillar pillar. By May 1987 the oral aphthae had healed. Another painful, smaller ulcer was noted on the left side of the perineum. The vestibular ulcer persisted.

Laboratory data included a hemoglobin of 8.9 gm/dl. The hematocrit was 28%. The white blood cell count was 5700/mm^3, with 30% lymphocytes and 69% neutrophils. Examination of a bone marrow biopsy specimen revealed only increased histiocytic activity. The serum levels of creatinine, urea nitrogen, alkaline phosphatase, bilirubin, transaminase, haptoglobin, glucose-6-phosphate dehydrogenase, and vitamin B_{12} were within normal limits. The erythrocyte sedimentation rate was 59 mm/hr. The serum iron level was 47 μg/dl with a total iron-binding capacity of 300 μg/dl. The urinalysis results were normal as were the prothrombin time and partial thromboplastin time. An electrocardiogram and results of chest radiographic examination were normal.

Repeated cultures of the genital and oral ulcers were negative for herpes simplex virus. The rapid plasma reagin and the fluorescent treponemal antibody tests were negative on two occasions. Gram-stained smears of the genital ulcer did not contain organisms suggestive of *Haemophilus ducreyi*. Two separate samples of serum contained antibodies to HIV, as determined by enzyme-linked immunosorbent assay and confirmed by Western blot. The CD4 cell count was 195 cells/mm^3 and the CD8 cell count was 1746/mm^3. There was no reaction to the intradermal injection of trichophyton or mumps antigens. Results of computed tomographic examination of the pelvis were normal. Microscopic examination of biopsy specimens from the vestibular ulcer disclosed acute and chronic inflammation, ulceration, granulation tissue, moderate dysplasia, and condylomatous changes. Cultures for acid-fast bacilli, actinomyces, and nocardia were negative. Cultures for HIV were not done.

The ulcer failed to respond to treatment with oral amoxicillin–clavulanic acid. Fever and a rash developed when the patient was given oral metronidazole and trimethoprim-sulfamethoxazole. In June 1987 treatment was begun with zidovudine 900 mg/day. One month later the dose was reduced to 600 mg/day. In association with zidovudine treatment the vestibular ulcer gradually reepithelialized (Fig. 2) and the genital warts partially resolved. No new oral aphthae or genital ulcers appeared.

Comment

We were unable to define an etiologic agent for the intractable genital ulcer in this HIV-infected woman. Our inability to find any evidence of syphilis, chancroid, herpes simplex virus infection, or other causes of genital ulcer disease, the failure of the lesion to respond to treatment directed at these established causes of genital ulceration, the nonspecific nature of the biopsy findings, and the healing of the ulcer in association with zidovudine administration all suggest that the ulcer may have been a manifestation of HIV disease.

As of March 31, 1990, 128,319 cases of HIV disease in the United States and its territories had been reported to the Centers for Disease Control.[1] It has been estimated that between 1 and 2 million Americans have already been infected with HIV.[2] Although the natural history of HIV infection is incompletely understood at present, it can be expected that unusual presentations of HIV disease will increase. Health care professionals must be aware of the ever-broadening spectrum of the disease.

Endometrial assessment by vaginal ultrasonography before endometrial sampling in patients with postmenopausal bleeding

S. R. Goldstein, MD, M. Nachtigall, MD, J. R. Snyder, MD, and L. Nachtigall, MD
New York, New York

Endometrial sampling is the mainstay of management of the postmenopausal patient with uterine bleeding. Thirty women with postmenopausal bleeding were studied prospectively. Before endometrial sampling, a vaginal probe ultrasonographic examination was performed. Eleven patients demonstrated a thin "pencil line" endometrial echo in which the maximum anteroposterior thickness on the long axis view was ≤5 mm. All eleven patients had minimal tissue obtained on biopsy and a pathology report of "tissue insufficient for diagnosis." Seventeen patients had an echogenic endometrium ≥6 mm. Pathology reports of their samples revealed tissue insufficient for diagnosis (two cases), proliferative endometrium (six), secretory endometrium (three), hyperplastic endometrium (three), polyp (two), and endometrial cancer (one case). Two additional patients had no endometrial echo visualized because of associated myomas. These findings suggest (1) that the absence of significant endometrial tissue (echo ≤5 mm) on vaginal ultrasonography in cases with postmenopausal bleeding is uniformly associated with tissue insufficient for diagnosis, and (2) when endometrial thickness is ≥6 mm the histologic diagnosis should be determined in the pathology laboratory. (Am J Obstet Gynecol 1990;163:119-23.)

Key words: Postmenopausal bleeding, histopathology, ultrasonography, vaginal probe ultrasonography

Endometrial cancer is the most common gynecologic malignancy yet also the one with the best survival statistics. Approximately 80% of endometrial cancer occurs in postmenopausal women. Because these patients usually are seen because of vaginal bleeding, it has been dogma in gynecology that the endometrium of postmenopausal women must be sampled. When the postmenopausal woman is taking hormone replacement therapy, such a rule should be modified. Much of the current clinical approach to such patients stems from the landmark paper of Padwick et al.[1] in 1986. They studied 102 women who were continuously receiving estrogen therapy and 12 days of progestin per month. They then correlated the day of onset of bleeding with the endometrial histology obtained by endometrial biopsy. In all cases, regardless of the dose or type of estrogen and progestin used, inappropriate histopathologic types (predominantly proliferative or hyperplastic endometrium) were always associated with bleeding before day 10 of the addition of the progestin. Secretory or absent endometrial tissue (the expected pathologic findings) was always associated with bleeding on day 11 or after. With the recently revealed benefits of hormone replacement therapy, the number of patients receiving therapy has increased.[2] Thus the total number of patients with inappropriate postmenopausal bleeding will also increase.

New vaginal probe ultrasonographic transducers are of higher frequency and closer proximity to structures being studied. This results in excellent near-field resolution, despite high degrees of magnification, thus yielding a type of "sonomicroscopy."[3] Previously investigators used high-resolution abdominal ultrasonographic equipment to assess uterine content.[4] We undertook this study to determine whether vaginal probe ultrasonography could demonstrate endometrial content in patients with abnormal postmenopausal bleeding and to correlate the vaginal ultrasonographic findings with the pathology of the tissue obtained by endometrial sampling.

Material and methods

This was a prospective pilot study. Thirty postmenopausal women with abnormal uterine bleeding were scheduled for outpatient suction endometrial sampling. Just before sampling a vaginal probe ultrasonographic examination was performed with either a 7.5 MHz Siemens Sonoline system, Iselin, N.J., or a 5.0 MHz Aloka 633 system, Tokyo. The uterus was scanned in long-axis and coronal views with special emphasis on the endometrium. The scanning of the uterus was first sagittal planes in an attempt to "section" the uterus from side to side to determine regularity of the endome-

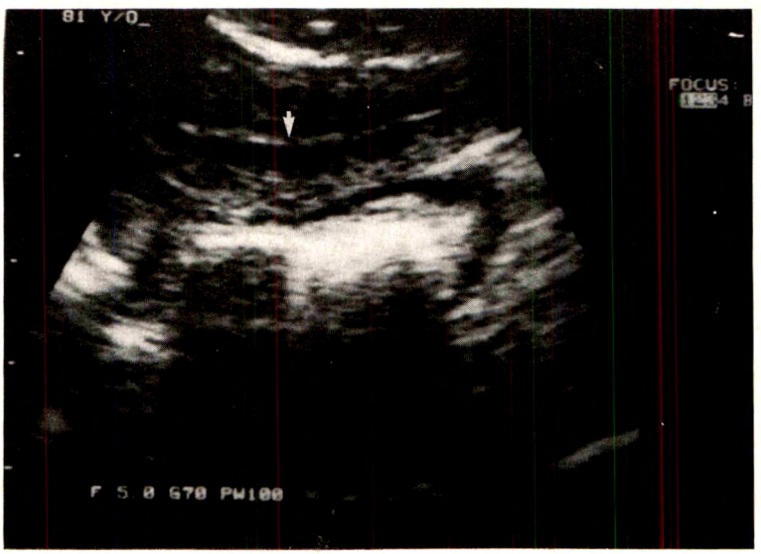

Fig. 1. Long-axis vaginal ultrasonographic views of an 81-year-old patient who had postmenopausal bleeding. The endometrial echo appears as a thin "pencil line" (1 mm) linear echogenicity *(white arrow)*. Notice the hypoechoic "halo" surrounding it. Endometrial sampling revealed tissue insufficient for diagnosis.

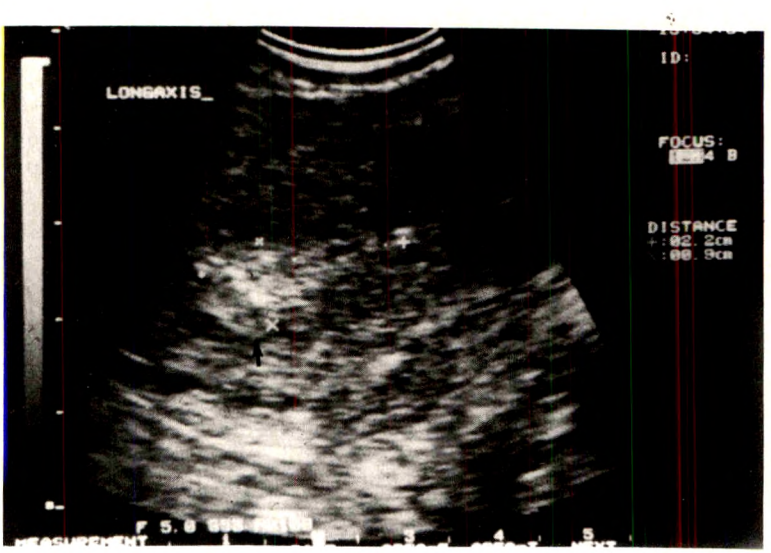

Fig. 2. View of a 55-year-old postmenopausal patient receiving hormone replacement therapy who consistently bled on or before day 6 of progestin. Anteroposterior thickness of the endometrium on this long-axis view was 9 mm *(black arrows)*. The pathology report on endometrial sampling revealed proliferative endometrium.

trium. The same maneuver was performed in a coronal plane. Anteroposterior measurements of endometrial thickness were taken from long-axis views to avoid oblique semicoronal views that might cause the endometrium to appear thicker. The entire pelvis was additionally examined to rule out any other gynecologic pathogic condition. Suction aspiration was then performed with a 3 mm stainless steel cannula (Vabra, Berkeley, Calif.). Care was taken to attempt to sample all areas of the endometrial cavity; tissue obtained was sent to the laboratory for pathologic examination.

Results

Thirty women (age range, 39 to 81 years) were studied. Twelve women had postmenopausal bleeding and were not receiving hormonal replacement therapy. The remaining 18 received estrogen/progestin replacement but had bled at inappropriate times according to the schemata of Padwick et al.[1] Ultrasonographic findings

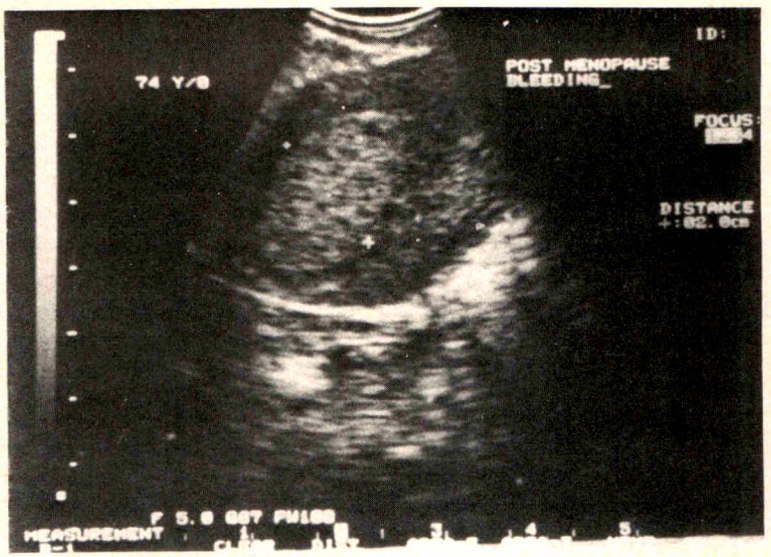

Fig. 3. A 74-year-old postmenopausal patient who was not receiving hormonal therapy presented with a history of postmenopausal bleeding. The long-axis vaginal ultrasonographic view here demonstrates anteroposterior thickness of endometrium of 2.0 cm *(between calipers)*. The pathology report on tissue obtained at endometrial sampling was glandular hyperplasia.

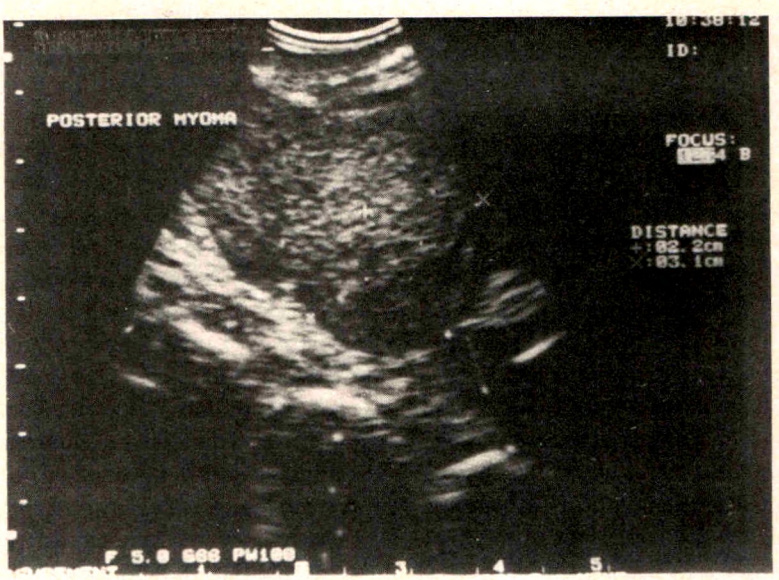

Fig. 4. A 59-year-old patient had postmenopausal bleeding. Bimanual examination revealed a normal-sized (upper limit), irregular uterus. A vaginal ultrasonographic view revealed a posterior myoma (3.1 × 2.2 cm). No endometrial echo could be identified. Endometrial sampling revealed proliferative endometrium with small foci of glandular hyperplasia.

revealed a thin "pencil line" linear endometrial echogenicity of 5 mm thickness total anteroposterior diameter in 11 patients (range, 1 to 5 mm). This was measured in the long-axis view (Fig. 1). Seventeen patients had an echogenic endometrium, measuring 6 mm, (range, 6 to 25 mm) (Figs. 2 and 3). In two patients endometrial echo could not be identified because of multiple myomas (Fig. 4). Pathology specimens in all 11 patients with endometrial thickness ≤5 mm was reported as "tissue insufficient for diagnosis" or "scant cellular material." In the 17 patients with endometrial thickness ≥6 mm, the pathology revealed proliferative endometrium (six cases), secretory endometrium (three), hyperplastic endometrium (three), polyp (two), tissue insufficient for diagnosis (two, and endometrial cancer (one). In the two additional patients

with no endometrial echo because of multiple myomas, one had tissue insufficient for diagnosis and the other showed proliferative endometrium with small foci of glandular hyperplasia, respectively.

Comment

It would appear from this preliminary study that endometrial thickness ≤5 mm maximum anteroposterior diameter measured on a long-axis view by vaginal probe ultrasonography is uniformly associated with minimal tissue obtained by sampling. In menopause the normal endometrium becomes thin and atrophic as a result of a lack of epithelial stimulation. The atrophic mucosa is prone to superficial punctate ulceration. This can result in "senile endometritis" and probably represents the cause of the bleeding when there is scant tissue present.[5]

It also appears from this study that when the endometrial thickness is ≥6 mm, a variety of pathologic diagnoses can be encountered. In such instances the histologic diagnosis therefore is made in the pathology laboratory, and not by ultrasonographic examination. When myomas preclude endometrial visualization, endometrial sampling remains mandatory.

A discrepancy may exist when significant endometrial tissue is present ultrasonographically (endometrial echo ≥6 mm) and the sampling reveals a diagnosis of tissue insufficient for diagnosis. This may cause great concern on the part of the clinician. In the past, whenever a diagnosis of tissue insufficient for diagnosis was encountered in the clinical context of postmenopausal bleeding, the question arose whether the operator had missed tissue because the endometrial cavity was not entered. In our study we had two patients in the group with endometrial echo ≥6 mm whose pathology report revealed tissue insufficient for diagnosis. Both patients had an endometrial echo measuring 6 mm. We used 5 mm as a cutoff point because although two patients with a 6 mm endometrial echo had tissue insufficient for diagnosis, there were several patients with 6 mm endometrial echoes who also exhibited proliferative endometrium.

The data from patients in this study who had a history of postmenopausal bleeding cannot be extrapolated to draw conclusions about mass screening of asymptomatic postmenopausal women. Further study is required to determine if an echogenic endometrium (≥6 mm) should be considered an indication for sampling in a nonbleeding patient. Thirty-five percent (5/17) of our patients who had bleeding and endometrial echos ≥6 mm had no significant pathologic findings (tissue insufficient for diagnosis or secretory endometrium). We also recognize that there are limitations of vaginal ultrasonography in the postmenopausal patient. It can be technically difficult to perform if the introitus has become stenotic. Coexisting myomas can obscure the visualization of the endometrial echo. We believe that measurements of the endometrial thickness should be made from the long-axis view. Such anteroposterior diameters are more reliable because the coronal plane, when obtained with vaginal probe ultrasonography, can actually be cut somewhat obliquely and reveal falsely elevated measurements.

Another possible shortcoming of our study was the fact that all patients had office sampling procedures, not formal curettage. There is the possible concern that such sampling procedures may be slightly less reliable than traditional fractional curettage.

There was only one malignancy in our series. This was an exophytic polypoid lesion that on vaginal probe ultrasonography did not suggest myometrial invasion. In most patients (Fig. 1) we observed the subendometrial halo of anechoic tissue described by Fleischer et al.,[4] but this was not a consistent finding. In no case was such a layer disrupted, but as mentioned previously there were no invasive lesions.

Six of the 17 positive scans produced pathologic tissue (hyperplasia, polyp, and cancer) for a positive predictive value of 35%, whereas none of the negative scans did (negative predictive value, 100%). This is similar to the experience in ovarian screening—a very sensitive but not very specific technique. We would submit, however, that proliferative endometria, although not conventionally thought of as "pathologic," are certainly not normal in a postmenopausal group regardless of the use of hormone replacement therapy.

Other important issues are raised by this work and should be considered in any further studies. We did not have the ability to follow up these patients longitudinally to determine the endometrial changes throughout the month with the administration of progestins, or precisely how the addition of steroids affects the density and thickness of postmenopausal endometria. Finally, the question of whether there would be ultrasonic resolution of proliferation with appropriate progestin therapy should be addressed.

This was a pilot study; obviously many more patients are required to confirm and extend these results. In this study 37% of patients (11/30) had thin "pencil line" endometrial echoes (≤5 mm in diameter). All 11 had tissue insufficient for diagnosis. If further study shows that such ultrasonographic findings are uniformly associated with a lack of significant endometrial tissue, then perhaps a large number of women could be reliably spared endometrial sampling and therefore avoid the risk, discomfort, and expense of the procedure. We also think that further studies with larger numbers of women, including those without a known history of vaginal bleeding and those not receiving hormone replacement therapy, must precede attempts to extrap-

olate the data to a screening situation. If these studies confirm our data, the use of endovaginal ultrasonography as a screening procedure before endometrial sampling should be considered.

Transabdominal and transvaginal ultrasonography in the diagnosis of ectopic pregnancy: A comparative study

Asko I. Kivikoski, MD, DSc, Carolyn M. Martin, MD, and James S. Smeltzer, MD
St. Louis, Missouri

Thirty-four patients believed to have ectopic pregnancies were examined by transabdominal and transvaginal ultrasonography. Twenty-five patients had tubal pregnancy confirmed operatively within 24 hours after ultrasonographic examination. In these cases adnexal findings highly suspicious for ectopic pregnancy were found in 68% of cases by transabdominal ultrasonography and in 84% by transvaginal ultrasonography. A distinct adnexal gestational sac was apparent in 32% of cases by transabdominal ultrasonography and in 64% of cases by transvaginal ultrasonography. Transvaginal ultrasonography was significantly more accurate ($p < 0.01$) in identifying an adnexal gestational sac and allows more detailed adnexal imaging. (AM J OBSTET GYNECOL 1990;163:123-8.)

Key words: Ectopic pregnancy, transvaginal ultrasonography, adnexal mass

Recent literature[1-3] has reported an increase in the incidence of ectopic pregnancies. The development of high-resolution ultrasonography and sensitive pregnancy tests has made it possible to diagnose ectopic pregnancy at an earlier stage of development than has previously been possible.

Transvaginal ultrasonography has been reported to be accurate in the evaluation of adnexal abnormalities[4,5] and ectopic pregnancies.[6,7] The diagnosis of tubal pregnancy by inclusion is sensible today, with the reported increase in both ectopic pregnancy and concomitant ectopic and intrauterine gestations.[8-10]

Recent reports in the literature have compared the ability of transabdominal ultrasonography and transvaginal ultrasonography to detect ectopic pregnancy.[11-17] These studies report findings in a heterogeneous population of patients with both normal and pathologic gestations. The purpose of this study was to prospectively compare the diagnostic accuracy of these two modalities in a pure population of operatively confirmed cases of ectopic pregnancy.

Material and methods

Thirty-four of all patients with suspected ectopic pregnancy, who were referred to the Perinatal Laboratory at Barnes Hospital from Jan. 1, 1988 to Jan. 4, 1989, were evaluated ultrasonographically both transabdominally and transvaginally. All these patients had a high index of suspicion for ectopic pregnancy on the basis of history of a previous ectopic gestation, prior tubal factor infertility, or previous tubal surgery. All of the patients had abdominal pain and/or vaginal bleed-

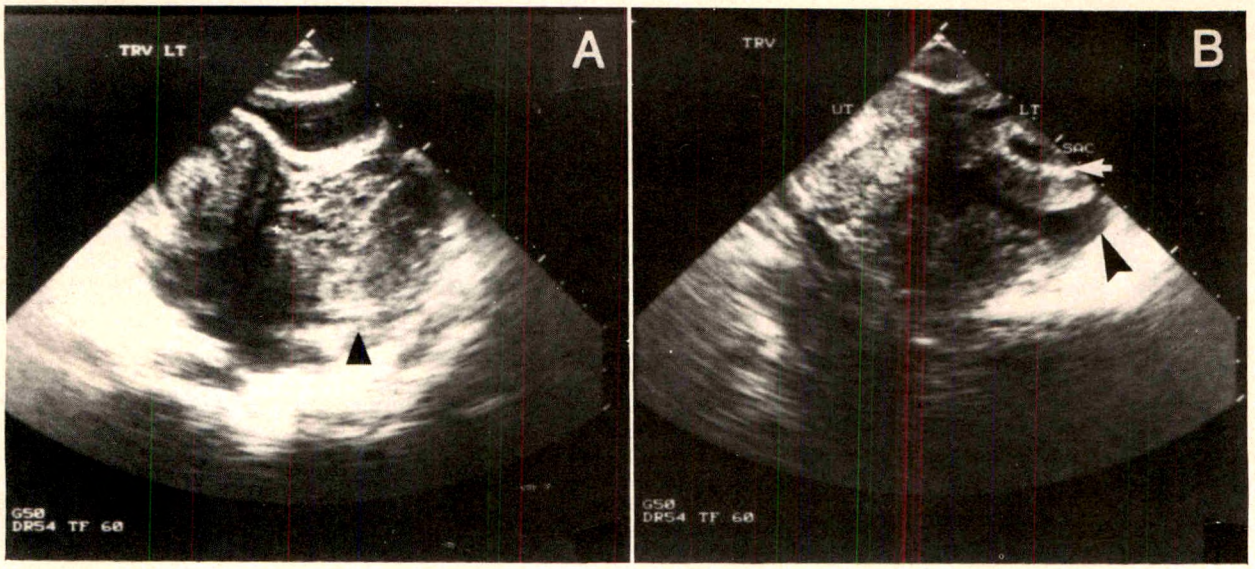

Fig. 1. A, Transabdominal transverse scan with a large, complex left adnexal mass *(black arrow)*. **B,** Transvaginal transverse scan of the same patient revealing a left adnexal gestational sac *(white arrow)* lying beneath the left ovary *(LT)*. Fluid is represented by *black arrow*.

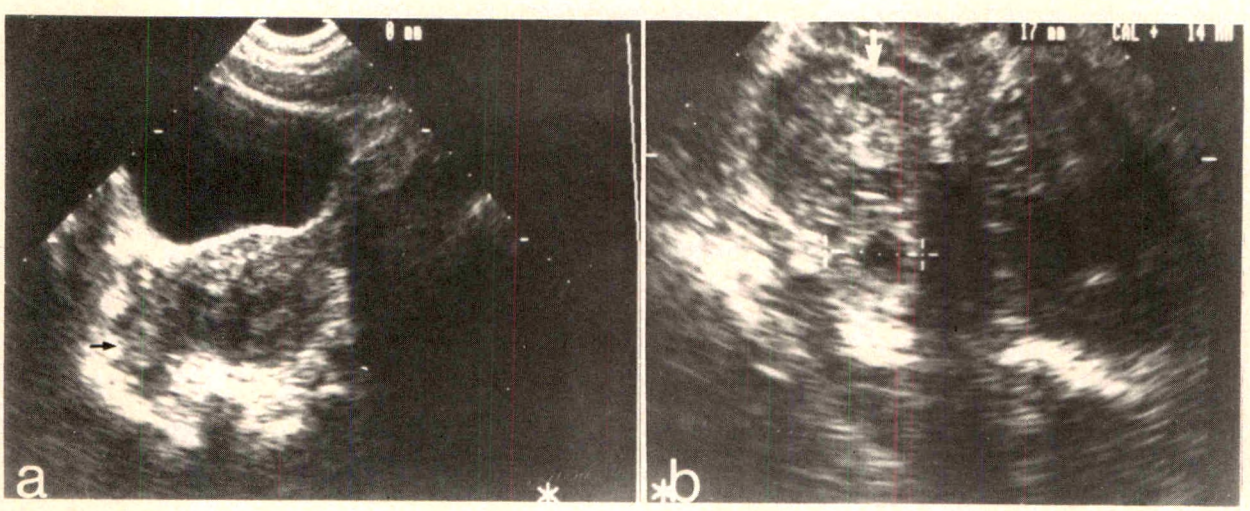

Fig. 2. a, Transabdominal transverse scan with an irregular right adnexal mass with echogenic focus posteriorly *(small black arrow)*. **b,** Expanded transverse scan of the same patient revealing an empty sac in the right adnexa *(electronic calipers)*. The right ovary *(white arrow)* is seen superiorly.

ing when first seen and were found to have a qualitatively positive urine or serum human chorionic gonadotropin (hCG) test result. All of the patients lacked an intrauterine gestational sac at the time of sonographic evaluation. In 9 cases the diagnosis of ectopic pregnancy was excluded on the basis of the lack of adnexal findings on ultrasonographic evaluation and at laparoscopy and/or the pathologic demonstration of villi at endometrial curettage. Laparoscopic examination was done in 6 of these 9 cases. One of those and the seventh patient had villi on endometrial curettage. Two others had only follow-up in their doctors' offices.

Twenty-five patients had a tubal pregnancy confirmed operatively and formed the subgroup of the study population that was operated on. These patients were first seen at 4 to 12 weeks of amenorrhea (mean 8.2 weeks) at the time of evaluation. The mean age of the patients was 28.5 years (range 18 to 39). Gravidity ranged from 0 to 8 (mean = 3) and parity was low (mean = 1), reflecting a large number of patients with

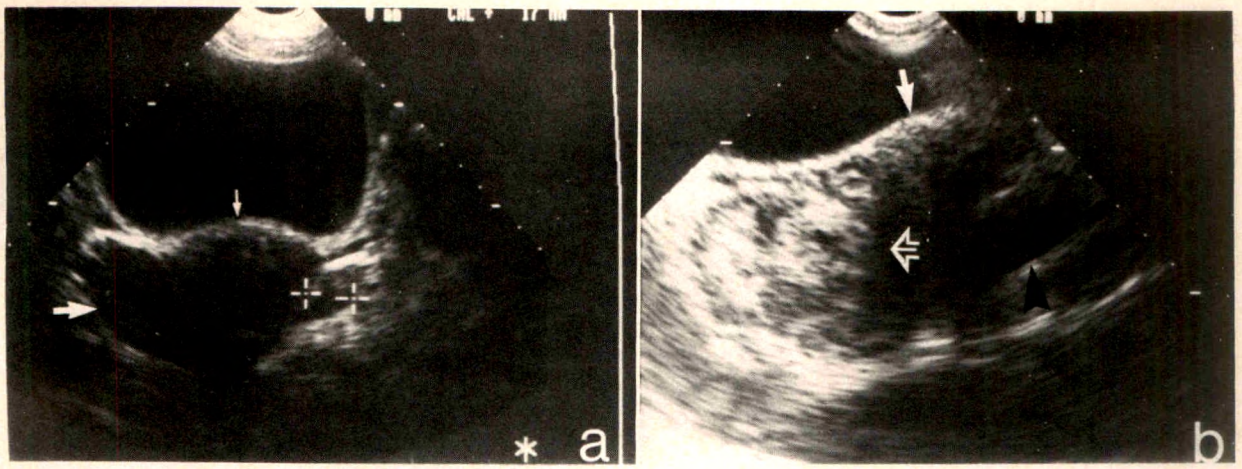

Fig. 3. a, Transabdominal transverse scan with a complex, noncystic right adnexal mass *(thick arrow)* lying immediately adjacent to the uterus *(thin arrow)*. The left ovary is marked by *electronic calipers*. **b,** Transvaginal transverse scan of the same patient showing a normal right ovary *(white arrow)*. infertility. All ultrasonographic examinations were performed by experienced sonographers and verified by a physician. Real-time scans were performed with an ATL UltraMark 4, with a 3.5 or 5.0 MHz abdominal sector transducer and a 5.0 MHz vaginal probe, or a Hitachi EUB-450, with a 3.5 MHz abdominal convex transducer and a 6.5 MHz vaginal probe. All patients were scanned initially with a standard transabdominal technique that included a full urinary bladder and systematic evaluation of the uterus, adnexal areas, and cul-de-sac. After this, the bladder was emptied and systematic transvaginal sonographic reevaluation of the pelvis was carried out.

The adnexal findings were described as (1) a gestational sac containing a fetal pole with or without heart motion, (2) an empty saclike structure surrounded by a thick rind of echoes, or (3) a complex or solid mass separate from a recognizable ovary (Figs. 1 to 3). All 25 of these patients underwent operation for confirmation of the sonographic findings within 24 hours of evaluation.

Results

In all 34 cases the uterus had no sonographic evidence of a gestational sac but pregnancy test result was positive. An endometrial cast of variable size (from 4 to 15 mm) was a common intrauterine finding in 25 cases of ectopic gestation. In 10 cases it was larger than 10 mm. In two cases (8%) intrauterine fluid collections were detected by both transabdominal ultrasonography and transvaginal ultrasonography. These were easily distinguished from a true gestational sac, however, by the absence of a double decidual sac sign.

Adnexal findings, which were highly suspicious for ectopic pregnancy in 25 operated cases, were shown in 17 patients (68%) with transabdominal ultrasonography and in 21 patients (84%) with transvaginal ultrasonography. This difference is not statistically significant, $p > 0.05$ (Table I). In the 17 patients with adnexal findings on transabdominal ultrasonography, 9 cases (36%) showed evidence of an adnexal mass separate from the ovary. Six (24%) of these masses were complex cysts and 3 (12%) were solid masses. A distinct adnexal gestational ring was apparent in only 8 cases (32%) with transabdominal ultrasonography. In the 21 patients with positive adnexal findings on transvaginal ultrasonography, a gestational ring was clearly demonstrable in 16 of the scans (64%). This difference is statistically significant, $p < 0.01$ (Table I). All of the 5 remaining patients (20%) were noted to have a complex or cystlike adnexal mass separate from the ovary. In all cases the sonographically positive adnexal findings were shown to be the site of the ectopic gestation at operation. The adnexal findings in all 34 cases are presented in Table II.

eration the tube was found to be adherent to the uterine fundus, omentum, and anterior abdominal wall and thus held out of the field of visualization by the transvaginal probe. The gestational sac was found to be separated from the ovary by transvaginal ultrasonography in 17 cases and by transabdominal ultrasonography in 7 cases.

When all 34 patients were screened by transabdominal ultrasonography and the sac or a mass separated from ovary was shown, sensitivity was 44%, specificity 100%, and positive and negative predictive values were 100% and 30%. By transvaginal ultrasonography the respective values were 72%, 100%, 100%, and 56%.

At the time of operation 20 (80%) of the patients had an intraoperative estimate of the amount of free blood or fluid in the cul-de-sac. In 19 of these cases we were able to measure the fluid from pictures (Table III). In the cases in which a small amount of blood was found at operation, transvaginal ultrasonography revealed either no demonstrable free fluid or a calculated amount <26 ml. Free fluid was observed in 12 patients (54%) by transabdominal ultrasonography and in 14 patients (64%) by transvaginal ultrasonography. The estimated amount of intraabdominal blood present at the time of operation ranged from 50 to 1500 ml over the entire study population.

Laparotomy was performed in 24 cases. The tube was unruptured in 86% of the patients, allowing conservative surgery for tubal salvage to be carried out. In the remaining case nonsurgical conservative management was used because of minimal sonographic findings and few symptoms. The decision was made to monitor the patient's serial quantitative serum hCG values, which fell to negative levels. The adnexal gestational sac was seen in 75% of unruptured cases by transvaginal ultrasonography.

Comment

All the patients in the study had a high index of suspicion for the presence of an ectopic pregnancy on the basis of past reproductive or gynecologic history, clinical presentation, and the presence of a positive qualitative pregnancy test result on either blood or urine. It has been reported that transabdominal sonographic visualization of a normal intrauterine pregnancy should be possible at first international standard β-subunit hCG levels in excess of 6500 mIU/ml.[18] Transvaginal visualization of an intrauterine gestational sac is possible at first international standard β-subunit hCG values >1800 mIU/ml[19] and at intact hCG levels >1000 mIU/ml on enzyme-linked immunosorbent assay.[20] Quantitative hCG levels were not known at the time of sonographic evaluation in our study population of 25 ectopic pregnancies. Because surgical evaluation was carried out within 24 hours after patients were first seen, quantitative hCG values, if determined at all, were only available in 11 cases in retrospect (range 139 to 6000 mIU/ml; mean 2176 mIU/ml). Because ectopic gestation represents an abnormal gestational state in which hCG levels frequently do not follow the normal incremental doubling pattern of an intrauterine pregnancy, the use of an isolated quantitative hCG level as a diagnostic tool in the ectopic

gestation may be limited. This may be particularly true of situations in which the length of amenorrhea is not known exactly and the quantitative hCG is at a subthreshold value. High-resolution transvaginal ultrasonography appears to be a powerful tool in the evaluation of suspected ectopic gestations because of its ability to demonstrate an intrauterine gestational sac very early in the course of gestation.[21, 22]

Nonovarian adnexal masses were visualized by transabdominal ultrasonography in 68% of cases and by transvaginal ultrasonography in 84% of cases in our population, demonstrating the improved efficacy of transvaginal ultrasonography over transabdominal ultrasonography. This improvement was more evident in the ability of transvaginal ultrasonography to visualize an adnexal gestational sac (64%) when compared with transabdominal ultrasonography (32%), $p < 0.01$. These results compare favorably with other reports in the literature.[11-17] The additive effect of using both imaging modalities is underscored in the single case where an ectopic mass was fixed by adhesions and could be visualized only by the abdominal scans. It is important to keep in mind that the high-resolution transvaginal transducers are limited in their imaging ability to structures that lie in the true pelvis and within their shorter focal zone. Thus it is prudent generally to use transabdominal ultrasonography to image the pelvis and document normal and abnormal anatomy and then use transvaginal ultrasonography for further detail of the pelvis with particular attention to any abnormal findings.

The presence of noncystic adnexal masses in cases of suspected ectopic gestation have been reported to have a higher positive predictive value than do cystic adnexal masses.[6] In our series the complex cystic mass was the more common finding. This may be explained by the fact that transvaginal ultrasonography allows a more detailed view of the true architecture of masses that appear solid on transabdominal ultrasonography.

Fluid was found in 54% of cases by transabdominal ultrasonography and in 64% by transvaginal ultrasonography. The ultrasonography was negative in most cases if there was <100 ml of blood in the pelvis at operation. Although 100 ml of blood should be readily visualized with transvaginal ultrasonography, the time from ultrasonography to surgical evaluation was typically several hours, and thus slow or early bleeding could have occurred during this interval.

Of greatest clinical significance is the fact that 86% of the patients had unruptured ectopic pregnancies that were amenable to treatment by salpingotomy, thereby saving the tube for future reproductive effort. High-resolution transvaginal ultrasonography appears to have much to offer in facilitation of the recognition of both intrauterine and ectopic gestational sacs. Earlier diagnosis of ectopic pregnancy enables the practitioner to achieve tubal salvage more frequently and allows the patient to escape the added morbidity of major intraabdominal bleeding.

In summary, transvaginal ultrasonography has added a new dimension to the early evaluation and diagnosis of ectopic pregnancy with enhanced ability to localize and identify an ectopic gestational sac, provide further architectural detail in the case of a complex adnexal mass, and allow more sensitive detection of small amounts of free fluid in the cul-de-sac. The clinical benefit to the patient is the greater opportunity of the physician to attempt and achieve tubal salvage. Because of the probability of distortion of normal pelvic anatomy in patients at risk for ectopic pregnancy, the additive value of systematic transabdominal and transvaginal scanning should not be ignored.

Niemann-Pick disease associated with nonimmune hydrops fetalis

Israel Meizner, MD, Arie Levy, MD, Rivka Carmi, MD,[a] and Charles Robinsin, MD[b]
Beer-Sheva, Israel

The number of metabolic disorders associated with nonimmune hydrops fetalis is very small and includes only Gaucher disease, GM_1 gangliosidosis type 1, Hurler syndrome, and mucolipidosis type I. We report another association of a nonimmune hydrops fetalis with Niemann-Pick disease as evident by electron microscopy, and wish to add this disorder to the list of conditions associated with nonimmune hydrops fetalis. (Am J Obstet Gynecol 1990;163:128-9.)

Key words: Nonimmune hydrops fetalis, Niemann-Pick disease

Nonimmune hydrops fetalis is a condition that affects non-Rh sensitized pregnancies, characterized by excessive fluid accumulation within fetal extravascular compartments and body cavities. The causes of nonimmune hydrops fetalis are numerous. In about 40% of fetuses, nonimmune hydrops fetalis is an idiopathic condition and no cause can be elicited.[1] Conditions associated with nonimmune hydrops fetalis include hematologic, pulmonary, neurologic, gastrointestinal, hepatic, genitourinary, infectious, neoplastic, cardiovascular, vascular, skeletal, chromosomal, and metabolic disorders.

The metabolic derangements associated with nonimmune hydrops fetalis are drawn from a number of pathways that involve either synthesis or storage disorders. The mechanisms for the development of hydrops in cases of storage disease may involve visceromegaly and obstruction of venous return.[2] The storage diseases that have been reported include Gaucher disease, GM_1 gangliosidosis type 1, Hurler syndrome (mucopolysaccharidosis I) and mucolipidosis I (sialidosis).

We recently encountered a fetus with nonimmune hydrops fetalis in which the cause could be attributed to another metabolic disorder not described in the English literature. The sonographic evidence of nonimmune hydrops fetalis was first documented at 19 weeks' gestation and included severe ascites and bilateral hydrothorax. The fetal liver appeared large and occupied most of the fetal abdomen. The patient refused pregnancy termination and did not agree to undergo either amniocentesis or percutaneous umbilical blood sampling. Repeated sonograms obtained at 25 and 30 weeks' gestation revealed worsening of the ascites and hydrothorax with appearance of marked skin edema (8 mm). Polyhydramnios was evident in all scans.

In utero fetal death was noted at 36 weeks' gestation. One day later the patient spontaneously went into labor and a severely hydropic neonate was vaginally delivered.

At autopsy a 1620 gm male infant with hydrops was

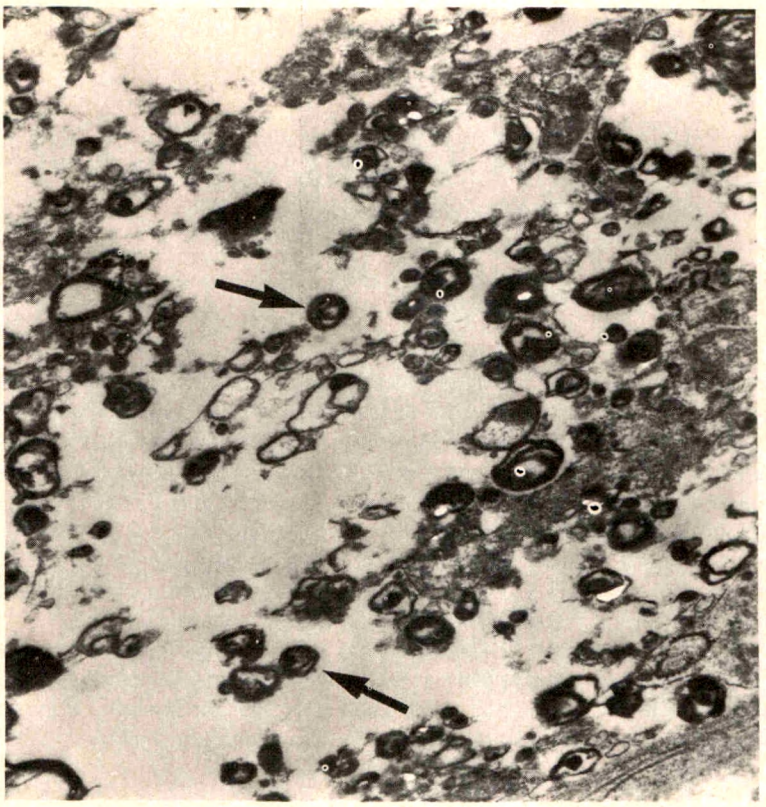

Fig. 1. Electron microscopic picture of cytoplasm of foamy cell from spleen shows many electron dense concentric lamellae *(arrows)*, granules, and tubular structures. (Original magnification × 20,000.)

noted. There were severe ascites, a hydrothorax, and generalized edema. The liver and spleen were greatly enlarged, filling the abdomen.

Microscopic examination showed 30% replacement of the liver and 80% replacement of the spleen by "foamy" histiocytes. Occasional "foamy" histiocytes were present in the marrow. There was also involvement of the neurons of the brain and spinal cord.

By electron microscopy (Fig. 1) numerous cytoplasmic inclusions were seen in "foamy" histiocytes in the liver and spleen. The inclusions were round or oval, small, and in groups. Some were discrete myelin-like figures that consisted of concentric osmiophilic lamellae or appeared as crystalline granules of lipid or as tubular structures, typical of Niemann-Pick disease.

Niemann-Pick disease is characterized by the accumulation of sphingomyelin in the reticuloendothelial cells of the liver, spleen, bone marrow, and lymph nodes. About 85% of the patients have the classic disease characterized by hepatosplenomegaly and intellectual deterioration that becomes manifest during the first year after birth, leading to death within 1 or 2 years. This disease has not been reported as a cause of nonimmune hydrops fetalis and therefore should be included in the list of metabolic conditions associated with this entity.

Risk factors for preterm premature rupture of fetal membranes: A multicenter case-control study

James H. Harger, MD,[a] Ann W. Hsing, PhD,[b] Ruth E. Tuomala, MD,[c] Ronald S. Gibbs, MD,[d] Philip B. Mead, MD,[e] David A. Eschenbach, MD,[f] G. Eric Knox, MD,[g] and B. Frank Polk, MD, MSc[b, †]

Pittsburgh, Pennsylvania, Baltimore, Maryland, Boston, Massachusetts, San Antonio, Texas, Burlington, Vermont, Seattle, Washington, and Minneapolis, Minnesota

To assess the association between women with preterm premature rupture of membranes and 41 potential risk factors, we conducted a case-control study in six United States tertiary perinatal centers. The study involved completion of a comprehensive questionnaire for 341 women with preterm premature rupture of membranes in singleton pregnancies from 20 to 36 weeks' gestation and 253 control women matched for maternal age, gestational age, parity, clinic or private patient status, and previous vaginal or cesarean delivery. Univariate analysis revealed 11 variables associated with a significantly ($p < 0.05$) increased risk of preterm premature rupture of membranes. After multiple logistic regression analysis, three variables remained in the model as independent risk factors: antepartum vaginal bleeding in more than one trimester (odds ratio 7.4; 95% confidence interval, 2.2, 25.6), current cigarette smoking (odds ratio, 2.1; 95% confidence interval, 1.4, 3.1), and previous preterm delivery (odds ratio, 2.5; 95% confidence interval, 1.4, 2.5). Cessation of cigarette smoking by pregnant women may reduce the risk of preterm premature rupture of membranes. Further study is necessary to determine the nature of the relationship between antepartum vaginal bleeding and preterm premature rupture of membranes. (Am J Obstet Gynecol 1990;163: 130-7.)

Key words: Premature rupture of membranes, cigarette smoking, preterm delivery

Premature birth remains the most frequent cause of perinatal morbidity and mortality in North America and Europe, and preterm premature rupture of the fetal membranes occurs in a significant proportion (15% to 40%) of preterm births.[1] The causes of preterm or low-birth-weight deliveries have been scrutinized and investigated intensively, but the majority of preterm births occur without an established cause. Several epidemiologic factors have been correlated with preterm labor but have been studied in surprisingly few reports.

Seven previously published studies have suggested various risk factors for preterm premature rupture of membranes.[2-8] These studies, however, were too small, uncontrolled, dated, or not specifically focused on risk factors for preterm premature rupture of membranes. For example, vaginal bleeding in any trimester and a history of preterm labor have been linked with the occurrence of preterm premature rupture of membranes. In an Australian study, vaginal bleeding during at least one trimester of pregnancy had occurred in 18 (30%) of 60 women with preterm premature rupture of membranes at 26 to 37 weeks' gestation.[2] A history of preterm delivery was found in the prior pregnancy of nine (20.5%) of the 44 multigravid women with preterm premature rupture of membranes. However, no control subjects were included in this study.

Cigarette smoking or a history of gynecologic surgery also have been implicated in preterm premature rupture of membranes. In a Swedish study of 3391 deliveries, 30 women with preterm premature rupture of membranes were compared with 30 control subjects matched for age, parity, duration of pregnancy, and socioeconomic status (all were middle class).[3] In this study bleeding in the first or third trimester ($p < 0.01$), smoking more than 10 cigarettes per day ($p < 0.01$), and previous gynecologic surgery ($p < 0.01$) were

found to be associated with an increased risk of preterm premature rupture of membranes. Four of the 30 cases of preterm premature rupture of membranes were twin gestations, whereas all of the controls were singleton pregnancies. In addition, a nonsignificant trend toward an excess number of prior therapeutic abortions was found in cases of preterm premature rupture of membranes compared with control subjects in this study. This trend agreed with the results of Koller and Eikhorn[4] who reported an increased risk of preterm premature rupture of membranes in women whose first pregnancy was voluntarily terminated by suction curettage ($p < 0.001$).

An analysis of data from the United States Collaborative Perinatal Project from 1958 through 1966 reported a statistically significant association between preterm premature rupture of membranes and prior surgery of the cervix, coitus at least weekly in the month before delivery, and histologic evidence of chorioamnionitis.[5] Cigarette smoking was associated with premature rupture of membranes at term but not with preterm premature rupture of membranes. Paradoxically, women who smoked 20 or more cigarettes per day had a slightly lower risk of premature rupture of membranes (6%) than those who reported smoking <20 cigarettes per day (7%). A significant association between cigarette smoking and preterm premature rupture of membranes and an association between cigarette smoking and abruptio placentae and placenta previa were reported by Meyer and Tonascia.[6] Others, however, found no such association between cigarette smoking and preterm premature rupture of membranes or abruptio placentae in a survey of 4440 women of varied socioeconomic status who were delivered in 1960 and 1961 in Charleston, South Carolina.[7]

Preterm premature rupture of membranes had also been linked in previous studies with indicators of intrauterine infection, such as the presence of *Bacteroides* species and histologic evidence of chorioamnionitis. *Bacteroides fragilis* organisms were isolated from the cervix, placenta, or amniotic fluid of 23% of women with preterm premature rupture of membranes but none of the controls.[8] Similarly, in a study of a predominantly black, lower socioeconomic status population in Brooklyn, a statistically significant association occurred between preterm premature rupture of membranes and the isolation of *Bacteroides* species in vaginal cultures ($p < 0.03$).[8]

We therefore undertook a prospective, multicenter, case-control study of preterm premature rupture of membranes. We used a comprehensive questionnaire among women in six tertiary perinatal centers in the United States to obtain detailed information about the risk factors for preterm premature rupture of membranes. This information will be used in the development of strategies for the prevention of preterm premature rupture of membranes and in the design of further studies about its cause, pathogenesis, and clinical management.

Methods

Study subjects. From 1982 to 1983 a multicentered case-control study was conducted by collaborating institutions including Brigham and Women's Hospital in Boston, Abbott-Northwestern Hospital in Minneapolis, University of Pittsburgh Magee-Womens Hospital, University of Texas Health Science Center Hospital in San Antonio, University of Washington Hospital in Seattle, and Medical Center Hospital of Vermont in Burlington. The Central Data Coordinating Center was located at The Johns Hopkins University School of Hygiene and Public Health, Baltimore. Women were recruited as study participants from patients admitted to participating medical centers with a diagnosis of rupture of the chorioamniotic membranes before the onset of labor at an estimated gestational age of <37 weeks. This estimate of gestational age was based on last menstrual period, early pregnancy tests, physical examination, and available ultrasonographic measurements of the fetus. Control subjects were obtained among women treated in local prenatal clinics or offices during the same period. Singleton controls who had intact membranes at the time of interview were matched to cases on the basis of age (within 4 years), gestational age (within 3 weeks), parity (nulliparous or multiparous), service (private or clinic), and history of cesarean section (yes or no).

Three hundred forty-one women with preterm premature rupture of membranes who met the inclusion criteria were enrolled in the study. The control subjects of the first 58 cases in Boston were enrolled according to different criteria than were subsequently used in the other centers; therefore these nonstandard controls were not entered into the data base. The 58 cases of preterm premature rupture of membranes were entered because the data were collected with the standard enrollment criteria and questionnaire. Nineteen of the 272 matched controls subsequently recruited for the study became ineligible because of ruptured membranes before 37 weeks' gestation ($n = 10$) or twin delivery ($n = 9$), leaving 253 eligible controls included in the final analysis. Control women who were excluded and those remaining in the study were similar in regard to demographic characteristics. A pretested standardized questionnaire was used by all study centers to interview cases and controls. Interviews were conducted by trained obstetrics and gynecology nurses who were not masked to the patient's clinical status. The study

Table I. Distribution of cases and controls by study center

Center	Cases		Controls	
	No.	*%*	*No.*	*%*
Boston	133	39.0	75	29.6
Minneapolis	14	4.1	0	0.0
Pittsburgh	87	25.1	85	33.6
San Antonio	59	17.3	46	18.2
Seattle	17	5.1	17	6.7
Vermont	31	9.1	30	11.9
TOTAL	341	100.0	253	100.0

was reviewed and approved by the institutional review boards at each participating institution.

Study variables. Information in the study was classified into categories as demographic variables, medical history (diabetes mellitus, anemia, renal disease, hypertension), gynecologic history (sexually transmitted disease, infertility, reproductive history), obstetric history (therapeutic abortion, spontaneous abortion, abnormality of uterus, route of delivery), current pregnancy history (prenatal care, maternal infection, physical activity, medication usage), and sexual behavior (number of sexual partners, age at first intercourse, sexual activity).

Premature rupture of membranes was defined as amniorrhexis >1 hour before the onset of labor. When cases and controls were questioned about obstetric history, preterm delivery was defined as delivery of an infant weighing <2500 gm at birth. This definition might include some infants that are born after more than 37 weeks from the last menstrual period but are below the 3rd percentile in weight (small for gestational age), but the definition was chosen as the most objectively reproducible. Hypertension was defined as an increase in systolic blood pressure ≥30 torr and an increase in diastolic blood pressure of ≥15 torr over the minimum blood pressure in the pregnancy. Anemia was defined as a hematocrit ≤30 vol %. Diabetes refers only to those patients who required insulin for glucose control before or during pregnancy.

Statistical analysis. In the univariate analysis, Fisher's exact probability test and χ^2 were used when appropriate to determine the statistical associations between case-control status and qualitative variables. The student *t* test was used to compare case-control differences for continuous variables. Multiple logistic regression was used for multivariate analysis to adjust simultaneously for covariates. Unconditional logistic regression was performed for the unbalanced group matching in which matching variables were included in the multivariate model to study their confounding effect, if present. Variables found to be statistically significant in the univariate analysis were entered in the multivariate model with other variables to examine their independent effects. Unless otherwise stated, the statistically significant differences were represented by a two-sided p value <0.05. Probability values shown in the tables were calculated by a 2 × N contingency table. The calculations were performed by SAS statistical program (Cary, N.C.).

Results

The distribution of cases and controls is shown by study center in Table I. Because the Minneapolis center contributed only 4% of the cases, the data were analyzed with and without Minneapolis cases; no substantial differences were found in the results. The demographic characteristics of the population are shown in Table II. The only significant difference was the greater proportion of cases of preterm premature rupture of membranes in all of the unmarried categories.

Physical and dietary comparisons of the cases and controls revealed no significant differences between the groups. Cases had a mean height of 161.8 ± 7.6 (SD) cm with a mean prepregnancy weight of 59.0 ± 11.1 kg and a mean weight of 76.1 ± 14.4 kg on admission with preterm premature rupture of membranes. Controls had a mean height of 163.6 ± 7.9 cm with a mean prepregnancy weight of 61.8 ± 14.9 kg and a mean weight of 73.3 ± 15.0 kg at the time of interview. There were no significant differences in ethanol ingestion between cases and control subjects even when subdivided into use of beer, wine, or distilled liquor and when subdivided by trimester. No significant differences were found between the groups in use of prenatal medications, antibiotics, prenatal vitamins, or oral iron supplements; however, the frequency of reported maternal anemia was greater in cases (16.2%) than in controls (9.2%) to a significant degree ($p = 0.01$). Measurements on hospital admission revealed that a hematocrit < 32 vol/dl was present in 20% of women with preterm premature rupture of membranes and 4% of control women. A hematocrit <30 vol/dl was present in 8% of women with preterm premature rupture of membranes and 2% of controls ($p < 0.05$).

Univariate comparison of the gynecologic and obstetric history revealed no significant differences be-

tween cases and controls in the number of previous term neonates delivered, previous spontaneous abortions, previous ectopic pregnancies, all previous gynecologic surgical procedures, and specifically previous cone biopsies of the cervix. When a history of infertility was sought by asking whether the patient had ever attempted to conceive without success for >1 year or if she had undergone medical or surgical therapy for infertility, 15.9% of cases and 10.4% of controls answered affirmatively ($p = 0.11$).

In univariate analysis significant differences in gynecologic and obstetric history were found between cases and controls in the total number of pregnancies, in parity, in number of previous preterm neonates delivered, in number of previous preterm neonates with premature rupture of membranes, in the number of previous curettage procedures, and in the number of cases with two previous elective abortions (Table III). When the patients and controls with two and with three or more elective abortions are combined and compared with those having a history of zero or one elective abortion, however, 7.5% of the cases and 3.1% of control subjects have had two or more elective abortions ($p = 0.08$). There was a minimal increase in the frequency of history of maternal diethylstilbestrol ingestion in cases of preterm premature rupture of membranes compared with controls, but the reason for the greater number of "unknown" responses in cases of preterm premature rupture of membranes was not clear. Because of the larger proportion of these "unknown" responses in cases, however, exposure to diethylstilbestrol in utero was related to preterm premature rupture of membranes ($p = 0.05$) in the univariate analysis and in the multivariate analysis.

Sexual behavior and its effects were studied with a series of questions, but only duration of time between membrane rupture and last sexual intercourse was significantly different in cases and controls (Table IV). Fewer cases (36.4%) than controls (53.6%) reported sexual intercourse within 1 week of the interview. The mean age at first intercourse was 18 years in both cases and controls. There was no difference between the

groups in the total number of previous sexual partners, in the frequency of oral-genital sexual contact, or in the frequency of sexually transmitted disease either preceding the pregnancy or occurring during the index pregnancy. Specific questions about a history of pelvic inflammatory disease, genital *Herpes simplex* infections, gonorrhea, *Trichomonas vaginalis* infections, *Candida albicans* vaginitis, and "nonspecific vaginitis" either before or during the index pregnancy failed to elicit any significant differences between groups. When *C. albicans* vaginitis and nonspecific vaginitis were excluded from consideration, the frequency of sexually transmitted diseases by history during the current pregnancy was 12.8% in cases of preterm premature rupture of membranes and 9.2% in controls ($p = 0.46$).

Patients with preterm premature rupture of membranes were asked about their activity at the time membranes ruptured. Fifty percent were asleep at the time of preterm premature rupture of membranes, 18% were sitting, and 26% were engaged in light or moderate activity. Only 1% of the cases were engaged in strenuous activities such as heavy lifting or jogging at the time of preterm premature rupture of membranes, and 5% could not recall their level of activity.

Characteristics most highly associated with preterm premature rupture of membranes in univariate analysis are presented in Table V. Vaginal bleeding in at least one trimester of pregnancy, cigarette smoking, anemia, hypertension, or diabetes during the index pregnancy were all associated with an increased risk of preterm premature rupture of membranes in the univariate analysis. Vaginal bleeding in at least one trimester of pregnancy occurred in 41.4% of cases of preterm premature rupture of membranes and in 17.3% of control women ($p = 0.0001$). In the multivariate analysis, previous preterm delivery, cigarette smoking, and vaginal bleeding during the index pregnancy were significantly associated with an increased risk of preterm premature

rupture of membranes (Table VI). Vaginal bleeding in any trimester, especially in the third trimester or in more than one trimester, is therefore an important marker for preterm rupture of membranes with a greater than sevenfold increase in risk for women with bleeding in more than one trimester.

Similarly, cigarette smoking during pregnancy was found significantly more often in cases with preterm premature rupture of membranes than in controls. Some smoking had occurred during pregnancy in 43.0% of cases but only 27.7% of controls ($p = 0.0006$). In the multivariate model there was a dose-response relationship observed with a 2.1-fold risk of preterm premature rupture of membranes in those women who had not stopped smoking. A history of previous preterm delivery was associated with a 2.5-fold risk of preterm premature rupture of membranes by multivariate analysis.

Comment

This study represents a large analytic epidemiologic study of risk factors for preterm premature rupture of the fetal membranes. Several features of this study strengthen the results and permit their application to a broad spectrum of situations and populations. First, the study includes patients from populations that are geographically, ethnically, and socioeconomically diverse. Second, the questionnaire used to obtain data was extensive and sophisticated. For example, the use of the Hollingshead index to delineate socioeconomic status is more precise than many more simple methods. In addition, the questionnaire was field-tested and improved in Boston before multicenter use. Third, the use of multivariate statistical analysis by logistic regression permits identification of significant independent variables. The results confirm and amplify some previous findings, but most important, they provide a basis

for further studies of methods to prevent and manage this vexing problem.

In agreement with other studies,[2, 3, 5, 6] we found that antepartum vaginal bleeding, history of preterm delivery, and cigarette smoking were related to an increased risk of preterm premature rupture of membranes. In a report published since we conducted our study, the association between smoking one or more packs of cigarettes per day and both abruptio placentae and preterm premature rupture of membranes was confirmed in a population of 30,596 women from the Northern California Kaiser Permanente Birth Defects Study.[9] In this study women who smoked one or more packs per day had a 2.2-fold increase in the risk of preterm premature rupture of membranes before 33 weeks' gestation and a 1.9-fold increase in abruptio placentae.

Chronic abruptio placentae provides a likely explanation for antepartum vaginal bleeding as a risk factor for preterm premature rupture of membranes. Because patients with preterm premature rupture of membranes are more likely to have hypertension, diabetes mellitus, and a history of cigarette smoking, all of which are risk factors associated with abruptio placentae, chronic abruptio placentae may account for both the vaginal bleeding and for increased uterine irritability and intrauterine pressure. An increase in intrauterine pressure could then cause preterm premature rupture of membranes over a local structural defect at the internal cervical os.[10, 11] However, the possibility of antepartum vaginal bleeding as merely a marker for preterm premature rupture of membranes cannot be excluded. It is possible, that antepartum vaginal bleeding is a separate manifestation of infection or other problem that primarily causes preterm premature rupture of membranes.

An association between preterm premature rupture of membranes, chorioamnionitis, and intrauterine infections has been reported previously.[3, 8] In these studies, *B. fragilis* organisms could be isolated from the cervix, placenta, and amnionic fluid in women with preterm premature rupture of membranes but was not found in controls. Histologic evidence of chorioamnionitis also has been linked to preterm delivery.[12] Recent evidence suggests that histologic evidence of chorioamnionitis can be found in 35% of women with severe abruptio placentae (i.e., those cases requiring immediate delivery).[13] Abruptio placentae could explain both antepartum vaginal bleeding and preterm premature rupture of membranes since preterm premature rupture of membranes and preterm labor probably represent a clinical continuum.

In agreement with two previous studies,[5, 6] we found that cigarette smoking during the index pregnancy increased the risk for preterm premature rupture of membranes. However, this finding contradicted results from a survey of 4440 women in South Carolina.[7] Cigarette smoke contains both carbon monoxide and nicotine, which may have a deleterious effect on the fetoplacental unit. Carbon monoxide combines with maternal and fetal hemoglobin with an affinity 210 times greater than that of oxygen, and it shifts the oxygen dissociation curve of fetal hemoglobin so that fetal oxygenation is reduced. Because nicotine causes arteriolar constriction, it could cause uterine decidual ischemic necrosis and subsequent abruptio placentae. Further studies of this proposed mechanism are necessary.

The increased risk of preterm premature rupture of membranes in women who continue smoking during pregnancy offers an exciting possibility for intervention. Both the dose-response relationship and the magnitude of the risk estimates suggest that pregnant women who smoke should be encouraged to stop smoking to decrease their risk of preterm premature rupture of membranes. A randomized clinical trial would be necessary to determine the magnitude of the decrease in risk of preterm premature rupture of membranes that can be achieved by the cessation of smoking.

Exclusion of the ineligible control subjects (24%) was a major limitation of this study. The comparisons of remaining controls with those excluded, however, revealed no substantial differences in demographic characteristics or risk factors between the two groups. Bias, if present, should therefore be minimal. The statistical power of this study is weakened by the reduced sample size, but the results and inferences should not be affected.

In summary, this study found that antepartum vaginal bleeding, history of preterm labor, and cigarette smoking during the index pregnancy are strong risk factors for preterm premature rupture of membranes. Further studies are necessary to explain these findings, but this study provides evidence that some action to reduce the occurrence of preterm premature rupture of membranes and its neonatal sequalae is possible. Strategies to help pregnant women cease cigarette smoking should be pursued vigorously, especially in patients with prior preterm premature rupture of membranes. In addition, precise determination of gestational age and careful antepartum fetal assessment should be performed in cases of antepartum vaginal bleeding in anticipation of the preterm premature rupture of membranes associated with such bleeding. Finally, methods to prevent preterm premature rupture of membranes should be focused on women at increased risk for the condition.

We thank Kathleen A. Lipscomb, RN (deceased), Chiara Barberi-Zanelli, MD, Mary Ellen Matulonis, RN, JoAnn Nielson, RN, and Deborah Hummel, RN, for assistance in conducting the patient interviews.

Necrotizing fasciitis of the total abdominal wall after sterilization by partial salpingectomy

Case report and review of literature

John P. Cederna, MD,[a] Brian W. Davies, MD,[b] Stephen A. Farkas, MD,[c] Joseph A. Sonta, MD,[d] and Teddy Sworniowski, MD[e]

Lewiston, Maine, and Barbertown, Akron, and Rootsdown, Ohio

A case of necrotizing fasciitis with full-thickness loss of the entire abdominal wall is reported after an uncomplicated sterilization by bilateral partial salpingectomy through a minilaparotomy incision in a healthy young patient. Salvage was accomplished by early wide surgical debridement and multiple reconstructive procedures. (AM J OBSTET GYNECOL 1990;162:138-9.)

Key words: Necrotizing fasciitis, total abdominal wall

Necrotizing fasciitis is a rapidly progressive, often fatal soft tissue infection involving the superficial and deep fascia with secondary involvement of the overlying skin as thrombosis of nutrient vessels occurs. The underlying muscle is spared until its entire facial envelope is affected late in the process.[1]

There are reports in the gynecologic literature of necrotizing fasciitis occurring after Bartholin abscesses,[2] vaginal delivery,[3-9] cesarean section,[3] abdominal hysterectomy,[10] sterilization by bilateral total salpingectomy,[11] and diagnostic laparoscopy[12] and spontaneously in the endopelvic fascia.[13] There are no reports of necrotizing fasciitis after sterilization by bilateral partial salpingectomy.

Case report

A 41-year-old, previously healthy woman was seen in the emergency room with severe abdominal pain, nausea, and vomiting. She had undergone elective sterilization by bilateral partial resection and ligation of the fallopian tubes through a suprapubic minilaparotomy incision (Pomeroy procedure) the day before. In the emergency room her temperature was 94.6° F, pulse 130 beats/min, respirations 48 breaths/min, and blood pressure 70/50 mm Hg.

Physical examination revealed a diffusely tender abdomen with guarding and rebound. Bowel sounds were absent, and the transverse suprapubic incision was slightly swollen and mildly erythematous with a large amount of drainage. The platelets count was 157,000/mm^3. Initial electrolytes were normal except for a carbon dioxide level of 15.3 mEq/L. Blood urea nitrogen and creatinine levels were 33 and 3.0 mg/dl, respectively. Liver function and amylase level were normal, whereas creatine phosphokinase was elevated at 972. Arterial blood gas levels on 6 L of oxygen via nasal cannula included Po_2 of 44.9 mm Hg, Pco_2 of 32.8 mm Hg, pH of 7.32, and bicarbonate of 16.8 mEq/L.

The patient was transferred to the intensive care unit; Swan-Ganz catheter (Baxter Edwards, Irvine, Calif.) and arterial lines were placed and fluid resuscitation was instituted. The patient received intravenous corticosteroids and broad-spectrum antibiotic coverage including ceftazidime, aztreonam, and metronidazole. Disseminated intravascular coagulopathy developed shortly after admission, and appropriate blood component therapy was instituted. Her condition stabilized to permit operation approximately 18 hours after emergency room presentation.

On operation extensive necrotizing fasciitis involving the entire abdominal wall without perforation of the bowel or uterus was found. The fallopian tubes showed evidence of recent surgical interruption with suture material in place. Abdominal hysterectomy with bilateral salpingo-oophorectomy and wide debridement resulted in a full-thickness defect of the entire abdominal wall.

6/1/20096

Cultures of infected abdominal wall tissue, urine, and blood grew an *Escherichia coli* organism sensitive to all antibiotics tested; anaerobic bacteria were not present. Postoperative treatment inclded a combination of piperacillin-gentamicin-clindamycin. The patient's condition stabilized, and further surgical debridement of the abdominal wall was required on the tenth hospital day with placement of a Vicryl mesh (Ethicon, Inc., Somerville, N.J.) over the omentum to slow the massive abdominal fluid loss.

Multiple reconstructive procedures began 15 days after the initial operative intervention. Reconstruction with bilateral tensor fascia lata myocutaneous flaps and polyglactin (Vicryl) mesh replacement was performed. Additional debridement and split-thickness skin grafting closed the abdominal defect completely. During the following year tissue expansion with flap advancement over polypropylene (Prolene, Ethicon) mesh to prevent abdominal hernia formation was done. Suction-assisted lipectomy to tailor the flaps was performed to complete the reconstruction.

Comment

Necrotizing fasciitis has been reported in all areas of the body.[14] There is no significant age or sex predilection.[15, 16] Clinically severe pain, swelling, and ill-defined cellulitis exhibit early. The overlying skin anesthetizes as a result of cutaneous nerve necrosis. Nutrient vessels to the skin are destroyed, causing the characteristic dull blue-gray areas, and blisters filled with hemorrhagic fluid. Tissue examination demonstrates widespread undermining of the skin, gray attenuated fascia, and pockets of serosanguineous fluid. Muscle necrosis develops later. Severe systemic toxicity accompanies these local findings.

The prognosis of necrotizing fasciitis directly relates to the speed of the diagnosis and wide surgical debridement of all devitalized tissue.[14] Once suspected, an incision should be made down to the underlying fascia. Extensive undermining of the skin confirms the diagnosis. Multiple linear incisions through the skin and subcutaneous fat are made until normal deep fascia is encountered. Debridement is adequate when finger dissection can no longer separate the subcutaneous fat from the fascia.[15, 17] Frequent evaluation of the wound by probing at the fascial level with a gloved finger is mandatory after operation.[17]

Empiric antimicrobial coverage should be based on the initial Gram stain results. If the smear shows a mixed picture, high-dose penicillin G or a semisynthetic penicillin to provide coverage against the streptococci plus an aminoglycoside or extended-spectrum cephalosporin for the *Enterobacteriaceae* infection and anaerobic coverage (such as clindamycin, chloramphenicol, metronidazole, imipenem-cilastatin, or β-lactamase–inhibiting penicillin for *Bacteroides fragilis* infection should be instituted pending culture results. If the smear reveals streptococcal organisms only, penicillin G is the antibiotic of choice. If an additional staphylococcal infection appears, use of a penicillinase-resistant penicillin such as oxacillin or nafcillin is recommended.[1]

The source of bacterial inoculum in our case was most likely the patient's skin. The upper genital tract is normally sterile, and the patient exhibited no symptoms or clinical evidence of salpingitis at the initial sterilization procedure. Although no prophylactic antibiotics were used, they are not usually indicated for routine tubal sterilization in an otherwise healthy patient without evidence of pelvic inflammation.[18] Infection should rarely occur in a patient with a competent immune system.

Relationship between plasma calcium fractions, other bone-related variables, and serum follicle-stimulating hormone levels in premenopausal, perimenopausal, and postmenopausal women

B. E. Christopher Nordin, MD,[a, b] Howard A. Morris, PhD,[a] Allan G. Need, MD,[a] Michael Horowitz, PhD,[c] and William G. Robertson, PhD[d]
Adelaide, Australia, and Riyadh, Saudi Arabia

The study comprises 186 untreated normal premenopausal, perimenopausal, and postmenopausal women in whom we measured serum follicle-stimulating hormone and a number of bone-related plasma and urinary variables. The calcium fractions in the plasma were calculated from the total calcium, albumin, globulin, anion gap, and bicarbonate concentrations. With a level of follicle-stimulating hormone within the reference range (up to 20 U/L) to define the premenopausal state, we confirmed previously reported menopausal rises in plasma calcium, phosphate, alkaline phosphatase, and bicarbonate, and in urinary calcium and hydroxyproline. However, inspection of the data, and *t* testing at different follicle-stimulating hormone criteria showed that these changes in bone-related variables did not generally occur until the level of follicle-stimulating hormone exceeded approximately 50 U/L. The plasma alkaline phosphatase level rose earlier than the other variables and was significantly elevated in subjects with follicle-stimulating hormone values above 30 U/L. The rise in plasma calcium was mainly a result of a rise in the ultrafiltrable fraction, which in turn was accounted for by rises in the ionized and complexed fractions, of which the complexed fraction was the most significant and proportionately the largest. The rise in the complexed fraction was accounted for by the increase in plasma bicarbonate. (Am J Obstet Gynecol 1990;163: 140-5.)

Key words: Menopause, plasma calcium, ionized calcium, follicle-stimulating hormone, urinary calcium

Although there are well-recognized changes in calcium metabolism at or about the time of the menopause, neither the primary event nor the stage in the climacteric at which it occurs has yet been established. We now report a cross-sectional study of normal premenopausal, perimenopausal, and postmenopausal women in whom we have measured the main plasma and urinary bone-related variables and compared them with the plasma follicle-stimulating hormone (FSH) level determined at the same time.

Material and methods

The series comprised 186 untreated normal women aged 32 to 60 years who first came to a menopause clinic with premenstrual tension or menopausal-type complaints, who were investigated by a standard protocol (see below), and who had no evidence of bone, kidney, or liver disease. Patients receiving corticosteroids or diuretics were excluded. Sixty-four of the women were still menstruating, albeit many of them irregularly; 17 had ceased menstruating within the past year; 52 had been amenorrheic for more than a year; 25 had had oophorectomy; and 28 had undergone hysterectomy with preservation of at least one ovary.

All the patients were tested at 9 AM after a 12-hour fast and after discarding their overnight urine samples. A venous blood sample obtained without a tourniquet and a fresh urine sample were collected. We measured FSH in the serum by radioimmunoassay; calcium, albium, globulin, alkaline phosphatase, sodium, potassium, chloride, and bicarbonate in the plasma were measured on the Technicon SMAC II (Tarrytown, N.Y.) with computer. The anion gap was calculated as the difference between the sum of the sodium and potassium concentrations and the sum of the chloride and bicarbonate concentrations. Calcium in the urine was measured on a centrifugal analyzer (Cobas-Bio Roche, Sydney, Australia), sodium by ion-selective electrode,

Ca, Calcium; *P*, phosphorus; *ALP*, alkaline phosphatase; *Ca/Cr*, calcium/creatinine; *OHPr/Cr*, hydroxyproline/creatinine; *Na*, sodium. Not significant: plasma albumin, globulin, bicarbonate, chloride, anion gap, protein-bound calcium, and urine sodium.
*Calculated.

hydroxyproline by the method of Bergman and Loxley,[1] and creatinine by the Jaffé reaction. Calcium and sodium excretion were expressed as the molar ratio to creatinine, and hydroxyproline excretion as millimole per micromole of creatinine. Calcium excretion was corrected for sodium by assuming a sodium/calcium molar ratio of 100:1.[2, 3] The reference range of FSH in premenopausal women in our laboratory is up to 20 U/L.

The calcium fractions in the plasma were calculated from the following equation by an iterative program based on the binding coefficients derived from our previous study of 556 normal postmenopausal women[4]:

$$[Ca^{++}] = T_{Ca} - \frac{0.01257[Ca]T_{Alb}}{1 + 0.01257[Ca^{++}]} - \frac{0.0049[Ca]T_{Glb}}{1 + 0.0049[Ca^{++}]} - \frac{0.00835[Ca]T_{AnG}}{1 + 0.00835[Ca^{++}]} - \frac{0.00759[Ca]T_{Bic}}{1 + 0.00759[Ca^{++}]}$$

where $[Ca^{++}]$ represents the plasma ionized calcium and T_{Ca} total calcium concentration in millimoles per liter, Alb and Glb represent plasma albumin and globulin in grams per liter, and AnG and Bic represent the anion gap and bicarbonate in millimoles per liter.

Statistical analysis was performed by one-way analysis of variance and by two-tailed *t* test using Minitab program 5.1 (Minitab, Inc., State College, Pa.) on a personal computer.

Results

The mean serum FSH levels in the five clinical groups are shown in Table I. Even in the 64 women who were still menstruating the mean FSH level was 28.7 U/L; 30 of the individual values were above the reference range. In all other groups, all FSH values were above the reference range except in three women aged 35, 40, 52 respectively, who had undergone simple hysterectomy.

The cases were then classified into premenopausal and perimenopausal or postmenopausal groups on the basis of their FSH level; up to 20 U/L was used as the criterion of the premenopausal state. There were 37 such women, of whom 34 were still menstruating (three were the simple hysterectomy cases mentioned previously). The mean values of the measured variables that differed significantly between the groups with normal and raised FSH levels are shown in Table II. The

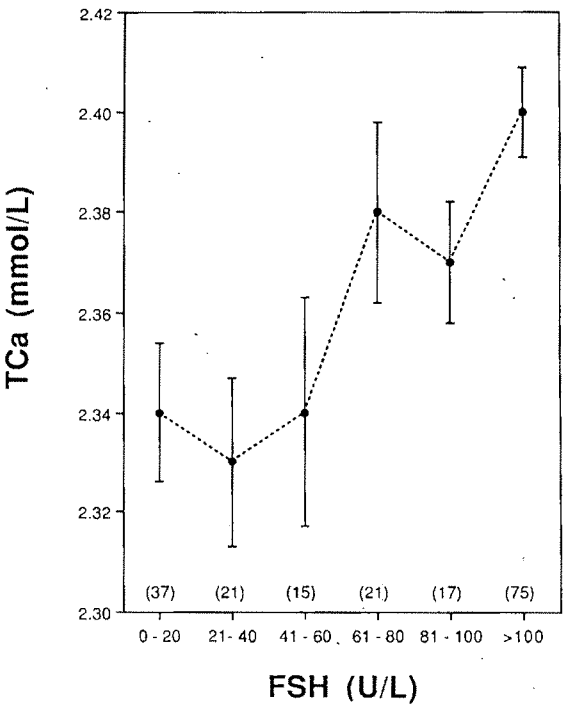

Fig. 1. Mean total plasma calcium *(TCa)* ± SE in patients grouped by FSH levels (the numbers in each group are indicated).

plasma calcium, phosphate, alkaline phosphatase, sodium, calculated complexed and ultrafiltrable calcium, urine calcium, and hydroxyproline were all significantly raised in the group with raised FSH.

Because inspection of the data suggested that these changes in variables occurred at a level of FSH higher than 20 U/L, the cases were then classified into six groups according to their FSH levels: 1 to 20, 21 to 40, 41 to 60, 61 to 80, 81 to 100, and >100 U/L, and the mean values of the measured variables were calculated in each group. Inspection of these data (of which the plasma calcium is shown in Fig. 1 and eight further examples in Figs. 2 and 3) indicated that the critical FSH value was approximately 50 to 60 U/L. Each variable was therefore retested at different FSH criteria (in steps of 5 U/L) to establish the criterion that yielded the highest t value when the means up to and above each criterion were compared. The results are shown in Table III. The variables in Table III are essentially the same as those in Table II except that the differences in bicarbonate and calculated protein-bound calcium, which were not significant at a level of FSH of 20 U/L, became significant at higher FSH criteria. For all the variables except plasma alkaline phosphatase, the FSH criteria for optimum discrimination between the mean values of variables at low and high FSH levels range from 55 to 70 U/L; for alkaline phosphatase the optimum criterion is 30 U/L.

It is also clear from Tables II and III (and from the figures) that the higher FSH criteria yield larger and more significant differences in most variables than are seen at an FSH level of 20 U/L. Thus the total plasma calcium differs only just significantly ($p < 0.05$) and by only 0.037 mmol/L when women with FSH values up to and above 20 U/L are compared; at an FSH criterion of 65 U/L, the absolute difference becomes 0.053 mmol/L and the statistical significance of the p value is reached at <0.001. Most of the t values for the other variables are also greater at criteria of about 60 U/L than at 20 U/L.

To confirm that the break point actually occurred at an FSH level of approximately 60 U/L, we performed one-way analysis of variance on the three lowest FSH groups and the three highest FSH groups separately. With none of the measured variables was the F value significant within either the lower or upper three FSH groups.

Comment

These observations can be separated into two categories: the nature of the change in calcium metabolism at the menopause and the stage of menopause at which it occurs. They are dependent on the validity of our calculation of the plasma calcium fractions, which represents a possible source of error.

We noted again the rise in plasma calcium at the menopause that we first reported in the early 1970s[5, 6] and has since been amply confirmed.[3, 7-11] It has always been assumed that this rise in total calcium reflects a rise in the ionized fraction, as has been reported by some workers,[8] but recent work has not confirmed this.[7, 9-1] We have previously shown that the ionized calcium calculated from the total plasma calcium and the concentrations of albumin, globulin, bicarbonate, and "anion gap" reflects very closely the measured ionized calcium.[1] In our previous study the rise in plasma calcium at the menopause was essentially caused by a rise in the complexed fraction. In this study of a different group of subjects, the rise in total calcium of 0.053 mmol/L (2.3%) when the FSH exceeds approximately 60 U/L is comprised of 0.017 mmol/L in the protein-bound fraction (2.1%) and the remainder almost equally divided in absolute terms between the ionized calcium (which rises 2.0%) and the complexed calcium (which rises 4.5%). These may seem to be small changes but the rise in ultrafiltrable calcium is more than enough to account for the rise in the fasting urinary calcium/creatinine ratio of 0.10. The rise in filtered calcium (0.037 mmol/L) is equivalent to about 0.26

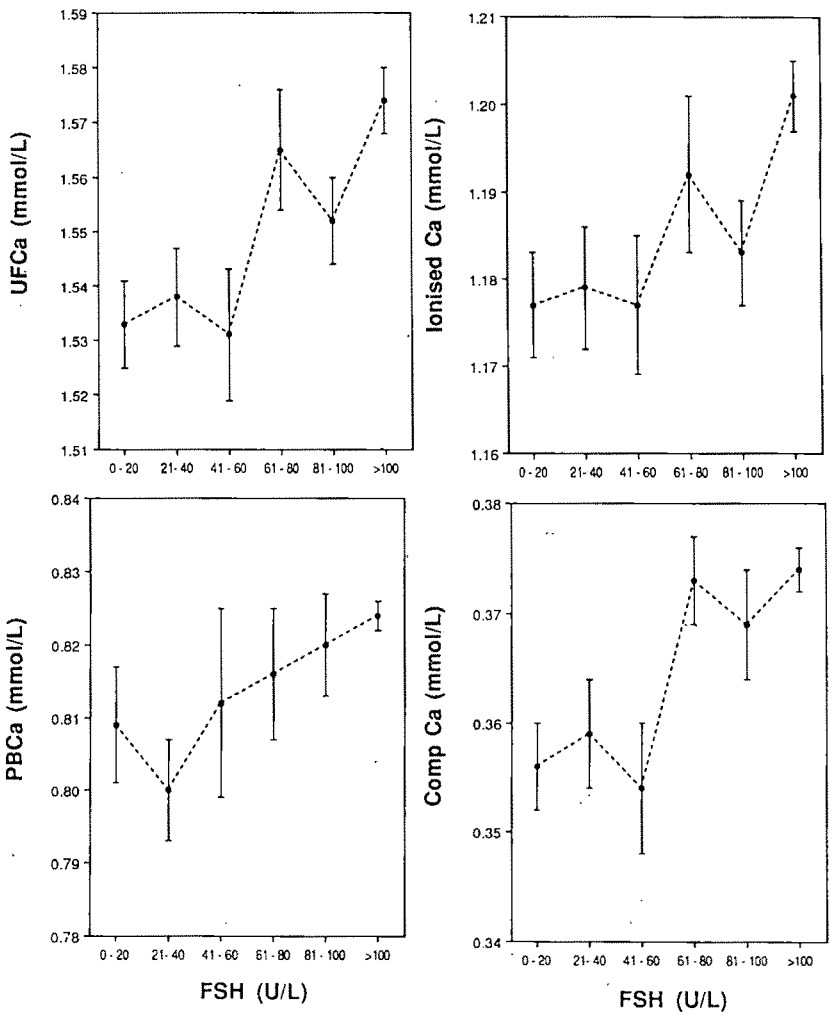

Fig. 2. Mean values ± SE of calculated ultrafiltrable calcium *(UFCa)*, ionized calcium, protein-bound calcium *(PBCa)*, and complexed calcium *(CompCa)* in the same subjects shown in Fig. 1.

Table III. Mean values of measured variables (± SE) in subjects below and above the FSH criterion yielding the highest t value

mmol/hr or 6.2 mmol/day at a glomerular filtration rate of 120 ml/min. Conversely, the rise in urine calcium only amounts to about 1 mmol/day. The increase in excreted calcium could therefore be accounted for by the increase in filtered calcium. The disproportionate rise in the complexed fraction of the plasma calcium is accounted for by the rise in plasma bicarbonate that has been noted previously[12] but has not attracted much interest. It could represent a mild metabolic alkalosis or respiratory acidosis. It is reversible by hormone administration.[11]

The significance of these findings in relation to the pathogenesis of postmenopausal osteoporosis is potentially great. The rise in plasma calcium at the menopause has variously been attributed to increased sensitivity of bone to parathyroid hormone in the absence of estrogen[13, 14] and to a change in the parathyroid gland set point for calcium.[15] Both of these explanations assume a change in the ionized fraction and fail to resolve what we consider to be the central issue: whether the increased urinary calcium after the menopause is the cause or result of the increase in bone resorption. If the rise in plasma calcium is largely a result of a change in the complexed fraction, it can hardly be secondary to increased bone resorption, and this would also explain why parathyroid hormone and 1,25-hydroxyvitamin D_3 levels do not change at the menopause.[16, 17] It also explains the rise in urinary calcium, even if there is no preferential excretion of the complexed fraction, which may be the case. However, interpretation is complicated by the small but significant rise in the ionized calcium fraction in our current data. This cannot be the primary event because it is much too small to explain the rise in the complexed fraction. However, neither can it be argued that the rise in complexed calcium is responsible for the rise in the ionic fraction; quite the reverse appears to be true. Resolution of this problem must await more information about the effect of the menopause on blood pH, which could have a profound effect on the interpretation of these

data, all of which assume a blood pH of 7.4. (It should also be noted that reports of unchanged measured ionized calcium at the menopause have corrected their readings to pH 7.4, whereas those that report a rise in measured ionized calcium have not made this correction.[11])

With regard to the stage of the climacteric at which the calcium changes occur, it is common practice to write and speak of "pre-" and "post-" menopausal women as though they moved abruptly from the one state to the other. This is only true of those who undergo oophorectomy. The remainder generally pass through a perimenopausal phase, when symptoms and hormone levels fluctuate, before they finally become truly postmenopausal. Our data show that the menopausal perturbation in all the bone-related variables except alkaline phosphatase occurs late rather than early (i.e., when the FSH level exceeds about 50 to 60 U/L). This is also implied by the data of Slemenda et al.[18] If we assume that the important hormonal event for bone at the menopause is the fall in estrogen levels, this would seem to imply that the FSH rises in the perimenopause before the estrogens have fallen sufficiently to affect the bone. Is it possible that the perimenopausal rise in FSH (seen in many women who are still menstruating) is a response to low inhibin levels rather than low estrogen levels?[19]

The rise in alkaline phosphatase seems to occur at an FSH level of approximately 40 U/L. It reflects both liver and bone function, but we are not aware of any change in liver function at the menopause. We cannot therefore explain why plasma alkaline phosphatase appears to rise at a slightly lower FSH level than does urine hydroxyproline.

Survival and outcome of infants weighing <800 grams at birth

Evelyn G. Lipper, MD,[a] Gail S. Ross, PhD,[a] Peter A. M. Auld, MD,[a] and Marc B. Glassman, PhD[b]

New York and Bronx, New York

This study reports on two aspects of outcome in a sample of infants whose birth weights ranged from 500 to 799 gm. First, maternal and early neonatal variables were analyzed by means of stepwise logistic regression. Five-minute Apgar score and initial pH were the only variables that predicted mortality at $p \leq 0.05$. Second, the surviving infants were examined at ages ranging from 17 months to 7 years. The majority (72%) had neurologic and/or developmental examinations in the suspect or abnormal range and required rehabilitation or early intervention services. (AM J OBSTET GYNECOL 1990;163:146-50.)

Key words: Prematurity, outcome, survival, extremely low birth weight

Since its inception in the early 1960s, the practice of modern neonatal intensive care has focused on infants with progresively lower birth weights.[1,2] Currently neonatologists are challenged by the improving survival of the extremely low birth weight infant (<1000 gm). Neonatology centers are reporting improving survival rates in this weight group, and attention to the neurodevelopmental outcome of the smallest of these infants, i.e., ≤800 gm, has been the subject of several reports.[3-11] To date, most studies have reported on outcomes of extremely low birth weight infants born from 1975 to 1980, with survival rates ranging from 20% to 50%. Rates of cerebral palsy range from 6% to 15%, and mean intelligence or developmental quotients appear to be lowered in many studies.

This study reports on two aspects of outcome in a sample of extremely low birth weight infants (<800 gm) born between 1980 and 1985: (1) the effect of maternal and immediate postnatal variables on survival and (2) the neurodevelopmental outcome of surviving infants.

Material and methods

Neonatal period. Between January 1980 and December 1985, 184 infants whose birth weights ranged from 500 to 799 gm were admitted to the Perinatology Center of The New York Hospital, a 55-bed neonatal intensive care unit. Forty-five percent of the infants were inborn, and the rest were transferred to the intensive care unit by a neonatal fellow and neonatal paramedic team from our neonatal intensive care unit.

Any infant who was discharged from the neonatal intensive care unit was considered a survivor, whereas all other infants were considered as non-survivors, even if death occurred beyond the first 28 days of life but still before discharge from the neonatal intensive care unit.

An analysis of the medical records of all inborn infants ($N = 80$) was performed to determine whether any maternal or early neonatal variables could predict survival. All inborn mother-infant pairs received intensive obstetric and neonatal care. Neonatal fellows attended all deliveries of extremely low birth weight infants and were responsible for assigning the Apgar scores and for resuscitating and administering subsequent intensive care to these infants. The majority of infants in this weight group did require resuscitation in the delivery room and underwent mechanical ventilation on admission to the intensive care unit. Initial pH values were obtained from the umbilical artery within the first hour of life. The neonatal fellow collected and recorded the data subsequently used for this study. The decision to include only infants born at our institution was made to ensure consistency of medical care and reliability of data collection.

Given that the outcome measure, mortality, was a binary variable, stepwise logistic regression analysis was used to predict mortality as a linear additive function of 21 independent variables. Before this analysis was conducted, the independent variables were examined for multicollinearity, and no serious collinearity problems were found. At each step in the analysis, the independent or predictor variable most strongly associated with mortality, controlling for the variables already in the equation, was entered if it was significantly associated with mortality at the $p \leq 0.05$ level.

Follow-up. An attempt was made to contact all of the

6/1/21411

surviving infants (inborn and outborn) who had been admitted to the neonatal intensive care unit. Forty-one of the 184 infants admitted to the neonatal intensive care unit (22%) were discharged home. Twenty-eight of the surviving infants underwent detailed neurodevelopmental evaluations at a mean age of 37 months (17 months to 7 years), including two children examined at neighboring institutions. Of the remaining 13 children who did not return for evaluation, four had died, two had moved out of the area, and five could not be located, including one child who had been placed for adoption. One child who lived out of the area was reported to attend regular kindergarten and to be receiving speech therapy. One additional child who was not evaluated was known to have cerebral palsy and developmental delay and was not included in the outcome data of this report.

Each child was examined by a developmental pediatrician who obtained a detailed history and performed a physical and neurologic assessment. On the basis of the neurologic assessment, the pediatrician classified each child as normal, suspect (e.g., mild to moderate but not disabling abnormalities of tone and reflexes, presence of abnormal movements), or abnormal (presence of cerebral palsy).

Measurements of length/height, weight, and head circumference were obtained and converted to percentiles by careful extrapolation from a published growth chart.[12] Children seen at <24 months of age were plotted according to their corrected age, whereas the growth measures of children over 2 years of age were not corrected for gestational age. The 50th percentile from the normative data was considered the norm for each group.

In addition, a developmental psychologist tested each child with either the Bayley Scales of Infant Development[13] (with both the Mental Developmental Index and the Psychomotor Developmental Index) or the Stanford-Binet Intelligence Scale (Form L-M, Revised),[14] depending on which test was most suitable given the age of the child. The Bayley Scales may be administered up through 30 months of age; the Stanford-Binet test begins at 2 years of age. Both scales have a mean of 100 and a standard deviation of 16. For the purposes of this report the scores on both the Bayley Mental Scales and the Stanford-Binet examination were combined to yield the mean and standard deviation of the mental development/intelligence quotient score for the total group. Again, correction for gestational age was made only until 24 months, after which developmental scores were calculated according to chronologic age.

Results

Predictors of mortality. Table I presents the demographic and perinatal variables that were used to develop the prediction model. Pregnancy complications such as previous failed pregnancies, multiple births, incompetent cervix, prenatal infection, and placental abnormalities were prevalent, and infants were more likely to be delivered by cesarean section than by vaginal delivery.

Table I. Demographic and perinatal description of 80 inborn extremely low birth weight infants born between 1980 and 1985

Demographic background	
Maternal age (mean ± SD)	28 ± 5
Race (nonwhite) (%)	43.8
Social class (%)	
Major and minor business and skilled craftsman	71
Semiskilled laborer	9
Unskilled laborer	20
Birth data and perinatal risk factors	
Survival	21
Gravida (mean ± SD)	2.9 ± 1.7
> 1 Previous failed pregnancy (%)	17.5
Multiple birth (%)	25
Preeclampsia-hypertension (%)	17.5
Placenta previa (%)	3.8
Abruptio placenta (%)	3.8
Incompetent cervix (%)	6.3
Infection (%)	18.8
Type of delivery	
Vaginal (%)	49
Cesarean section (%)	51
Birth weight (gm, mean ± SD)	686 ± 82
Gestational age (wk, mean ± SD)	25.8 ± 1.8
Male sex (%)	46.3
Head circumference (cm, mean ± SD)	22.6 ± 1.4
Length (cm, mean ± SD)	31.8 ± 4.9
1 min Apgar score	3.2 ± 2.4
5 min Apgar score	5.1 ± 2.1
Initial pH (mean ± SD)	7.27 ± 0.13

Table II presents the estimates of the final stepwise logistic regression, their χ^2 values, and statistical significance levels, as well as a descriptive measure "partial R" of the net strength of the association of each predictor with mortality. As indicated in the table, only two of the variables, initial pH ($p \leq 0.029$) and 5-minute Apgar score ($p \leq 0.030$), are statistically significant at $p \leq 0.05$. Taken together, the joint predictive power of these two independent variables is 0.153 ($p < 0.001$). The negative signs of these variables indicate that relatively low scores on each predictor are associated with an increased probability of dying.

A more precise statement of these relationships can be made by comparing the odds of dying for infants with differing Apgar scores and pH values. For each unit increase in Apgar score, controlling for initial pH, the odds of dying decrease 1.38-fold or by 27%; for each 0.1 increase in pH, controlling for Apgar score, the odds of dying decrease 1.85-fold or by 46%.

A closely related way of expressing the relationships

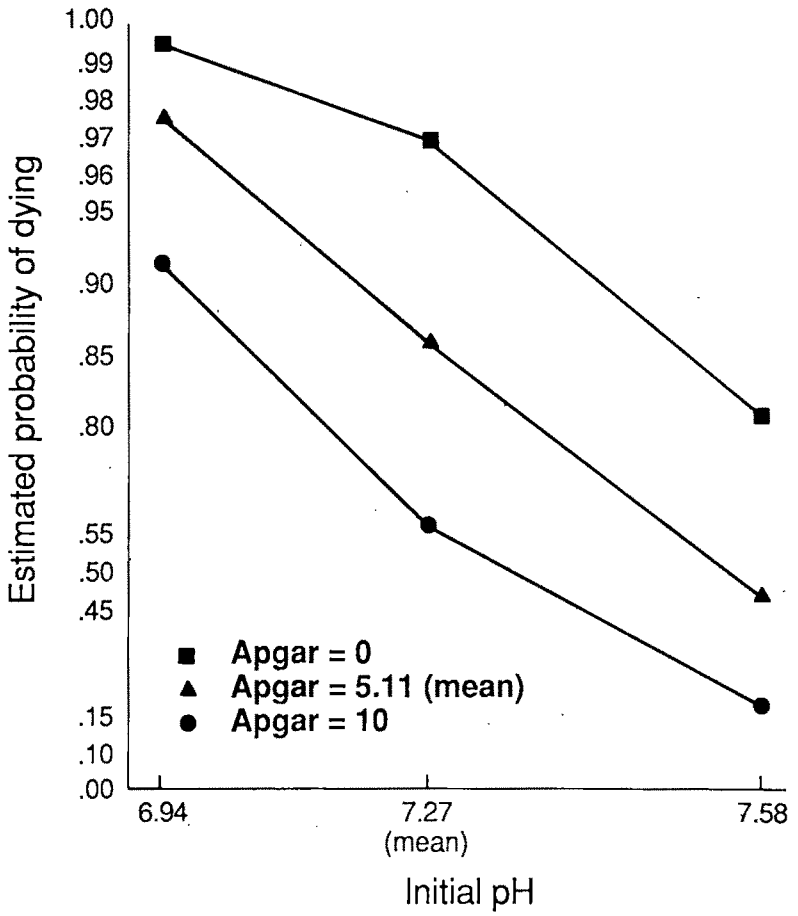

Fig. 1. Estimated probability of dying as a function of initial pH and 5-minute Apgar score.

among mortality, Apgar score, and initial pH is to graph the estimated probability of dying as a function of the latter two variables. As is indicated in Fig. 1, infants with low scores on both variables have substantially greater probabilities of dying than infants with high scores.

Long-term outcome. With regard to neurodevelopmental outcome, Table III shows that only 8 of 28 (28%) children could be considered completely normal (normal results of neurologic examination and mental ability scores ≥85) at the follow-up visit. Seventeen children (61%) had suspect results of neurologic examinations and/or mental development/intelligence quotient scores between 71 and 84. Three children (11%) had cerebral palsy and a mental development/intelligence quotient score of ≤70. Seventeen children had received or were receiving special services in the form of physical, occupational, and speech therapy or special education. Other residual problems included visual impairment (including retrolental fibroplasia, myopia, and strabismus) and attention-deficit hyperactivity disorder, accompanying other neurologic and developmental abnormalities, in 10 of 11 cases.

The children also had significantly lower percentiles in height and weight. Totals of 59% and 63% of children had heights and weights, respectively, below the 10th percentile, whereas only two children had either height or weight above the 50th percentile. Three children had microcephaly (head circumference below the 2nd percentile). Of these, two had mental development/intelligence quotient scores below 65.

Comment

Our analysis of 21 maternal and early neonatal variables revealed that only 5-minute Apgar score and initial pH were significant predictors of mortality in this cohort of infants. Although several previous studies[15-17] have examined the influence of perinatal factors on survival in the <1000 gm infant, we have confined our observations to those infants weighing between 500 and 799 gm. It is important to look at influences on mortality in this group apart from the 800 to 1000 or 1000 to 1500 gm infants to better define which obstetric or neonatal practices impact mortality in the extremely low birth weight infant.

Amon et al.[18] reported on the development of a prognostic model in 476 inborn infants with birth weights

Table II. Stepwise logistic regression model

Variable	*Regression coefficient*	χ^2	*p*	*Partial R*	R^2	*p*

≤1000 gm, born during 1980 to 1985. The most important variables that predicted survival were birth weight, 5-minute Apgar score, gestational age, cervical dilatation on admission, and race. Ales et al.,[19] using a similar model, analyzed all singleton pregnancies resulting in viable live-born infants weighing ≤1500 gm at birth. Here, birth weight and 5-minute Apgar score gave the greatest predictive accuracy. The definiton of viability was not specified in this study, and it is possible that many of the infants included in our analysis who died soon after delivery would have been eliminated from the study of Ales et al., thereby biasing their sample toward infants of larger birth weights and more advanced gestational age.

Our study confirmed the importance of the 5-minute Apgar score in predicting survival. Logistic regression analysis demonstrated that low Apgar scores were associated with an increased risk of dying. The Apgar score,[20] devised as a method to evaluate the need for resuscitation in the delivery room, provided an evaluation of the infant's general condition at birth and its ability to adapt to extrauterine life. It is a simple tool from which probability of death can be predicted, even in the extremely low birth weight infant.

Likewise, the initial pH obtained in the first hour of life served as an additional predictor of mortality. Infants in this study who were severely acidotic had a substantially increased risk of dying. The initial pH reflects the ability of the fetus to withstand the birth process without significant asphyxia and acidosis, as well as its ability to be adequately ventilated. In other words the physiologic maturity of the infant is what determines survival in this group of extremely low birth weight infants, and Apgar score and initial pH best reflected this developmental maturation.

Birth weight and gestational age in this group were no longer significant predictors because they no longer conferred additional meaningful maturity. Whether the Apgar score and initial pH can be significantly improved by obstetric and neonatal intervention and thereby lead to improved survival remains to be studied further.

With regard to the infants weighing <800 gm who survived, their outcome results are comparable to those of other centers reporting on infants born up through 1980.[3-11] This report is of a cohort of children admitted later, from 1980 to 1985, yet the 72% rate of overall handicap and the 9.8% mortality rate after neonatal intensive care unit discharge remain equally high. The years from 1980 onward represent a period in which there has been a concerted effort to improve the viability of the smallest infants, with concomitant interventions in perinatal management. Our results on outcome and those most recently published by Hack and Fanaroff[21] suggest that it may be difficult to effect improvements in morbidity among this group of smallest infants, despite refinements in neonatal intensive care.

Higher survival rates in infants of increasingly smaller birth weight signify that a greater number of infants will have neurologic and intellectual impairments that will require specialized intervention programs, both during the early years of life and throughout the school years. Of particular note here was the relatively high number of children with intelligence

quotients in the suspect category (between 71 and 84), indicating that the children will not be severely impaired in intellectual ability but that they will require special educational services. Studies of infants <1500 gm[22-25] have already shown a significantly higher prevalence of neurologic impairment, mental retardation, learning disabilities, sensory deficits, and behavior problems than is found in the normal population of children. When compared with the very low birth weight group (<1500 gm) the extremely low birth weight infants show about double the rate of neurodevelopmental problems.

We also demonstrated a shift toward lower percentiles in the heights and weights of the children who survived: >50% of children fell below the 10th percentile for both measures. Whether the growth of these children will approach a more normal distribution as they reach school age will be subject to further investigation. Studies reporting on the growth achievement at school age of infants ≤1500 gm at birth are conflicting, with some investigators reporting catch-up[26] and others not.[27]

Given the very-high-risk status of <800 gm infants, it is imperative that they be followed up carefully through school age. Looking toward the future, we can anticipate the need for expansion of resources for special education because of increasing numbers of children with special needs.

The differential neonatal morbidity of the intrauterine growth retardation syndrome

José Villar, MD, MPH,[a, c] Mercedes de Onis, MD, PhD,[a] Edgar Kestler, MD, MSc,[b, c] Fernado Bolaños, MD,[c] Rolando Cerezo, MD,[c] and Heinz Bernedes, MD, MHS[a]

Bethesda, Maryland, Atlanta, Georgia, and Guatemala, Guatemala

This is a prospective study of differential morbidity among subgroups of intrauterine growth retardation. Cases of intrauterine growth retardation (N = 3450) (≥37 weeks, <10th percentile birth weight for gestational age) were classified by their ponderal index (weight/length^3) in four subgroups using the 10th, 25th, and 90th percentiles of the Lubchenco's ponderal index-gestational age distribution. There were 432 cases (12.5%) with low ponderal index or disproportionate intrauterine growth retardation, 936 (27.1%) with intermediate ponderal index, 2030 (58.8%) with adequate ponderal index or proportionate intrauterine growth retardation, and 52 (1.5%) with high ponderal index. The low ponderal index group or disproportionate intrauterine growth retardation group had a statistically significant higher risk (between 1.6 and 12.5 times) for low 1- and 5-minute Apgar scores, aspiration syndrome, hypoglycemia, and perinatal asphyxia than the adequate ponderal index group. The low ponderal index group also had an increased risk (relative risk = 2.0 [95% confidence interval, 1.0 to 3.8]) for hospital stay of more than 1 week. These differences persist after a stratified analysis by birth weight and in a multiple logistic regression analysis. Similarly, higher neonatal morbidity is observed among infants with normal birth weights but with low ponderal index. These data provide further evidence of the heterogeneity of the intrauterine growth retardation syndrome and of the independent effect of body disproportion on neonatal morbidity, even among infants with normal birth weights. Because there are significant clinical implications attributed to the low ponderal index group, this subgroup should be identified as early as possible. (Am J Obstet Gynecol 1990;163:151-7.)

Key words: IUGR, ponderal index, neonatal morbidity

Infants with intrauterine growth retardation (IUGR) are at higher risk than their counterparts with normal birth weights for perinatal and infant morbidity and mortality as well as for congenital malformation.[1-3] It has been proposed that the group with IUGR is not homogenous and subclassifications with the weight/length ratio or ponderal index have been offered.[4-6]

These classifications differentiate at least two groups: those with IUGR and low ponderal index, wasted or disproportionate IUGR and those nonwasted, with proportionate growth retardation or adequate ponderal index.[7] The former group, associated with a shorter period of growth retardation, shows weight reduction but less marked reduction in length. The latter group has experienced fetal growth retardation in both weight and length.

In recent years several publications have shown that the cases of proportionate and disproportionate IUGR tend to have different epidemiologic characteristics,[8-9] as well as neonatal[10-11] and postneonatal growth and mental development patterns.[7, 12] Furthermore, a series of recent reports[13-17] after early suggestions by Scott and Usher[18] also demonstrated a differential neonatal morbidity of the subgroups of growth-retarded newborns. These reports show that the disproportionate (low ponderal index) IUGR group has higher neonatal morbidity, particularly hypoglycemia, perinatal asphyxia, hypothermia, and fetal distress and meconium aspiration than the proportionate IUGR group.

In this article we describe the neonatal morbidity found in a large cohort of infants with IUGR (as classified by their birth weight/length relationship) and the association between anthropometric characteristics of intrauterine growth retardation and early neonatal complications.

Material and methods

This was a prospective follow-up study of 16,850 pregnant women who had their first prenatal visit be-

tween April 1984 and January 1986 at the antenatal clinic of the Gynecology and Obstetrics Hospital of the Guatemalan Social Security Institute, Guatemala. A detailed description of this population and its health care characteristics has been published elsewhere.[19, 20] This is an urban, predominantly working-class population and women eligible to receive Social Security health benefits include those women who are formally employed and wives of employed men.

The Gynecology and Obstetrics Hospital is a tertiary level 230-bed hospital where all deliveries of infants of eligible women who use the Social Security system occur. The hospital is staffed with obstetrics-gynecology residents and trained obstetricians for prenatal and delivery care. All cesarean deliveries and high-risk deliveries are attended by pediatric-neonatology residents.

Birth weight, length, head circumference, and gestational age by physical examination were obtained immediately after birth from all newborns by a team of specifically trained neonatal nurses. Birth length measurements were taken on a standard measuring table as previously described.[10] Gestational age by physical examination was calculated with a simplified version of the Dubowitz method.[21]

A standardization process was completed before initiation of data collection and a data quality control system was implemented during the study period for all variables and anthropometric measurements studied. The newborn information had excellent reliability and very low measurement errors.[22, 23]

All clinical assessments of neonatal morbidity were determined by a senior neonatologist and recorded in the neonatal intensive care unit precoded summary form. A trained research clerk abstracted the data daily and completed the study data collection form in consultation with a senior neonatologist (R. C.) and the study field director (F. B.). The nurses and neonatologists were only aware that an epidemiologic study was being conducted, but they were not informed of the specific hypotheses being tested.

Of the 16,850 women enrolled in the study, 362 were excluded because they either did not have complete data, or one of the newborn anthropometric values was >3 SDs for this population. There were 16,488 singleton live births with complete information on anthropometric characteristics and gestational age at delivery. Six hundred ten (3.7%) births were preterm (<37 weeks) and are not considered in this analysis. The term population (≥37 weeks) was divided as infants with normal birth weights (N = 12,428) or term intrauterine growth retarded (N = 3450, 21%) if above or below the 10th percentile of a sex-specific birth weight for gestational age distribution from a well-nourished population.[24] Infants were further classified into four groups by their ponderal index values ($weight/length^3$)[6] according to the 10th, 25th, or 90th percentile of a ponderal index for gestational age distribution.[25] These groups constitute the subjects of this report.

Neonatal morbidity identified up until discharge from the hospital or the neonatal intensive care unit was the dependent variable. The morbidity information available in the precoded summary form included: *1- and 5-minute Apgar scores* determined by either a neonatal nurse or a pediatric resident; *length of hospital stay* in days; *perinatal distress* as an overall clinical evaluation based on at least one of the following: abnormal fetal heart rates, Apgar score ≤6 at 5 minutes, more than a trace of meconium-stained amniotic fluid at the time of membrane rupture in a nonbreech presentation, or newborn acidosis; *hypoglycemia* (≤35 mg/dl within 72 hours after birth) among those infants with IUGR admitted to the neonatal intensive care unit (N = 221); *aspiration syndrome* as diagnosed by the presence of meconium in the trachea while suctioning the airway after birth; clinical manifestations of aspiration (e.g., respiratory distress) and chest x-ray films; *hyperbilirubinemia* (>15 mg/dl), and any *neonatal infection,* including meningitis, by clinical diagnosis and laboratory confirmation, reported as present/absent, age at diagnosis, localization and, when possible, type. In addition, events related to labor and delivery such as rupture of membranes; duration of labor; use of oxytocin, anesthesia, or other drugs; type of delivery; and amniotic fluid characteristics were also recorded.

The incidence of morbidity for the ponderal index subgroups was calculated and are presented for the total population and stratified by birth weight. Adjusted odds ratios were obtained with logistic regres-

sion analysis[26] for each morbidity indicator with the IUGR/adequate ponderal index group as the reference.

Birth weight, length, gestational age, and ponderal index expressed in a continuous form were further included as independent variables in a multiple regression logistic[26] model aimed to predict each of the neonatal morbidity indicators.

The a priori hypothesis that infants with intrauterine growth retardation and low ponderal index (disproportionate IUGR), independently of birth weight, have higher neonatal morbidity than those with adequate ponderal index (proportionate IUGR) was tested.

Results

There were 432 (12.5%) infants with low ponderal index (IUGR-LPI); 936 (27.1%) intermediate ponderal index (IUGR-IPI); 2030 (58.8%) adequate ponderal index (IUGR-API); and 52 (1.5%) high ponderal index (IUGR-HPI). Among the normal birth weight term group (n = 12428) 1.06% were of low ponderal index, 9.8% of intermediate, 82.0% of adequate ponderal index, and 7.1% of high ponderal index.

The mean birth weight of the IUGR-LPI group was lower than the other three groups with IUGR; however, the IUGR-LPI group was taller than the other groups, whereas the IUGR-HPI group was significantly shorter ($p < 0.01$). The IUGR-HPI group had a mean length of 40.8 ± 4.0 cm (Table I). It included nine infants who were less than 36 cm, three of whom had congenital malformations. Given the small sample size and the abnormal number of congenital malformations, this group will be excluded from the morbidity analysis.

First stage of labor lasting more than 12 hours was more common among the IUGR-LPI group (15% versus 11%) ($p < 0.02$) and this group also had higher rates of forceps or vacuum deliveries (3.3%) than the IUGR-API group (1.6%) ($p < 0.01$). Elective cesarean section were higher in the IUGR-API group (3.8%) than the IUGR-LPI group (1.4%) ($p < 0.05$). The low ponderal index-IUGR group had higher incidence of meconium-stained amniotic fluid (18.9%) than the intermediate ponderal index (14.4%) and the adequate ponderal index groups (9.5%) ($p < 0.01$).

Table II presents the incidence of neonatal morbidity for the IUGR subgroups. For all morbidity indicators, rates were highest for the low ponderal index group and lowest for the group with API-IUGR. There is also a statistically significant trend in rates of morbidity from the LPI-IUGR group to the API-IUGR group.

To explore the independent effect of low birth weight and ponderal index, we further stratified the IUGR population by birth weight level (≤2500 gm and >2500 gm) and compared within each stratum the LPI-IUGR with the API-IUGR subgroup.

There were 213 LPI-IUGR and 489 API-IUGR infants among those with birth weights ≤2500 gm. The mean birth weights were 2214 (±264) gm vs 2338 (±152) gm and the mean lengths were 47.5 (±0.4) cm versus 44.7 (±0.8) cm for the groups with low ponderal index and adequate ponderal index, respectively. There were 219 LPI-IUGR and 1541 API-IUGR in the group with birth weights >2500 gm. The mean birth weights were 2666 (±114) gm versus 2718 (±114) gm and the mean lengths were 49.8 (±1.1) cm versus 46.9 (±1.0) cm for the groups with low ponderal index and adequate ponderal index, respectively.

In addition, the population with normal birth weight (>10th percentile birth weight for gestational age) was also classified by ponderal index level according to the same reference standard.[25] There were 132 infants with

‖Up to hospital discharge.

low ponderal index and normal birth weight; 10,192 infants with adequate ponderal index and birth weight above the 10th percentile of birth weight for gestational age. The mean birth weights were 3035 (±255) and 3268 (±313) gm and mean lengths were 51.8 (±1.6) and 49.3 (±1.5) cm for the groups with low ponderal index and normal birth weight and adequate ponderal index and normal birth weight, respectively. The mean gestational ages were 39.3 (0.8) weeks for the group with low ponderal index and normal birth weight and 39.3 (±0.7) weeks for the group with adequate ponderal index and normal birth weight.

As seen in Table III, the low ponderal index groups (either IUGR or normal birth weight) have, in the three comparisons, higher neonatal morbidity than the groups with adequate ponderal index. Interestingly, the morbidity ratio between the low ponderal index and adequate ponderal index subgroups increases with increasing birth weight. For example, the group with LPI-IUGR ≤2500 gm has 2.5 times higher risk for 1-minute Apgar scores ≤3 than its API-IUGR counterpart; the LPI-IUGR >2500 gm group has 3.8 times more risk of low Apgar score than the group with API-IUGR >2500 g. Finally, the low ponderal index-normal birth weight group has 9.8 times higher risk of low Apgar score than the group with adequate ponderal index-normal birth weight (Table III).

Table III also presents data on the incidence of major congenital malformations diagnosed by neonatologists before discharge from the hospital. There were 106 infants diagnosed in these subgroups with an overall incidence of 0.8%. No differences were observed between infants with low ponderal index and adequate ponderal index at any level of birth weight.

Table IV presents birth weight adjusted odds ratios for the morbidity variables. These odds ratios represent the increased risk over the IUGR-API group and are adjusted by birth weight, which is known to be associated with neonatal morbidity among infants with IUGR.[27] This adjustment allows for the evaluation of the independent effect of the IUGR anthropometric characteristics on neonatal morbidity. Again, the IUGR-LPI group experienced higher risks for morbidity with the exception of hyperbilirubinemia, as compared with the IUGR-API group (low 5-minute Apgar score, hypoglycemia and infection did not reach $p < 0.05$ level). The IUGR-IPI group had values in between. An inverse trend clearly emerges in these tables between neonatal morbidity and ponderal index.

Finally, analyses were also performed for the newborn anthropometric measurements expressed as continuous variables. High negative correlation coefficients were observed between ponderal index and infant length ($R = -0.67$; $p < 0.001$). Thus, in the logistic regression analysis, only ponderal index, birth weight, and gestational age are included as independent variables. Each morbidity indicator is used as a dependent variable.

Perinatal distress: Overall clinical evaluation based on at least one of the following: abnormal fetal heart rate patterns (auscultation), low Apgar score, meconium-stained amniotic fluid, and neonatal acidosis.

*Presence or absence of the characteristics.

†Adjusted regression coefficient with standard error in parentheses; logistic regression analysis.

‡$p < 0.01$.

§$p < 0.05$

‖$p < 0.10$

As can be observed in Table V, ponderal index was negatively associated with all indicators of neonatal morbidity, reaching statistically significant levels, after adjusting by birth weight and gestational age, in all of the morbidity indicators, with the exception of hyperbilirubinemia, hypoglycemia, and infections. As expected, birth weight was also negatively and significantly associated with all indicators of neonatal morbidity. To summarize, the ponderal index level, independently of birth weight and gestational age, is negatively associated with neonatal morbidity among term infants with intrauterine growth retardation.

Conversely, gestational age in this population of term (≥37 weeks) infants with intrauterine growth retardation is positively associated with all neonatal morbidity indicators except hyperbilirubinemia and infections (Table V).

Comment

We have presented evidence from a large prospective study that the level of disproportionality (weight/length ratio) among infants with IUGR and normal birth weight is an independent predictor of neonatal morbidity, after adjusting by birth weight. This evidence is observed when ponderal index is expressed by percentile level groups (low to adequate) or as a continuous variable: the lower the ponderal index, the higher the neonatal morbidity.

The IUGR-API or proportioned IUGR group could include a number of normal, yet small infants, representing the lowest end of a normal distribution of fetal growth. This could partially explain the lower morbidity observed in this subgroup as compared with the LPI-IUGR groups. Although this may be the case among well-nourished populations that have reached their full growth potential, it is unlikely to represent a large proportion of the group with intrauterine growth retardation in underprivileged populations.[9] Infants with intrauterine growth retardation-adequate ponderal index from both developed and developing populations score lower in developmental tests compared with infants IUGR-LPI and normal birth weights.[7, 12] This would not be expected if these infants were only genetically smaller.

Nevertheless, data for Table III also suggests that the API-IUGR group weighing >2500 gm may include a number of infants that are genetically small and not growth retarded. This group had similar early neonatal morbidity to the adequate ponderal index-normal birth weight group. Both figures are considerably lower than those of the group with adequate ponderal index intrauterine growth retardation with birth weights <2500 gm.

The heterogeneity of fetal malnutrition is similar to the subgroups described among malnourished children (wasted-stunted) and contributes further to support the biologic similarities between intrauterine and extrauterine malnutrition.

Preliminary studies, all based on small sample sizes, support the differential morbidity pattern reported here for the IUGR subgroups. The IUGR-LPI group experienced higher rates of meconium-stained amniotic fluid, meconium aspiration,[13] fetal distress,[17, 18] perinatal asphyxia and low Apgar score,[14-17] and as also observed here, increased risk for intrapartum interventions.[17]

Infants with disproportionate IUGR also have higher incidence of hypoglycemia than the IUGR-API group, confirming previous reports.[13-16] These infants, with acute malnutrition or wasting, similar to children with an acute caloric restriction during childhood, have been shown to have insufficient glycogen liver stores[4] and diminished subcutaneous fat reserves.[27, 28] This is aggravated by their higher rate of perinatal distress resulting in a reduced gluconeogenic response to hypoglycemia. In contrast, infants with proportionate IUGR, similar to stunted children, tend to have adequate glucose homeostasis.

The increased morbidity of the disproportionate growth-retarded infants is in agreement with the higher neonatal and perinatal mortality that has been observed in this subgroup.[29, 30] For example, in two populations from developing countries, infants with disproportionate IUGR had between 2.0 and 2.8 times higher risk of early neonatal mortality.[29] Similarly, asymmetrically formed infants from Norway had 4.6 times greater perinatal mortality than those with appropriate weight and length.[30]

We have provided evidence of the heterogeneity of the IUGR population, suggesting that the ponderal index effect may be present among infants with normal birth weight. It should be remembered, however, that the morbidity patterns of IUGR are different at different postneonatal ages. The group with disproportionate IUGR-LPI has higher neonatal morbidity, as was demonstrated here, whereas the group with proporionate IUGR-API experiences higher rates of abnormal postneonatal growth and development.[7, 10, 12]

In this analysis no differential effect was observed in relation to congenital malformations by ponderal index level. The effect of IUGR on congenital malformations is the subject of a more detailed study currently being conducted.

Finally, the analysis presented in Table V shows that neonatal morbidity of term infants with intrauterine growth retardation (≥37 weeks) is positively associated with gestational age: neonatal morbidity is higher the longer the infant remains in utero after 37 weeks. These data support the recommendation of delivering infants with IUGR when they reach pulmonary maturity.[31] This recommendation appears to be more important among infants with disproportionate IUGR who are at higher morbidity risks.

This study lends support to the importance of early antenatal identification of IUGR and it subgroups with the use, for example, of ultrasonographically determined anthropometric ratios.[17, 32] This could provide additional information for a more adequate perinatal management including, if necessary, the early delivery of infants with LPI-IUGR.

We thank Dr. Rolando Figueroa, head of the Neonatology Unit, Guatemalan Social Security Hospital, Gloria Garcia, RN, and William Calvert, MPH, for their contributions to this project.

Growth of linear parameters in trisomy 18 fetuses

Sabine Droste, MD,[a] Jack FitzSimmons, MD,[b] Julie Pascoe-Mason, BS,[c] and Thomas H. Shepard, MD[c]

Seattle, Washington, and Madison, Wisconsin

Linear growth in fetuses with trisomy 18 has not been systematically described. We studied the relationship between long-bone, crown-rump, and foot length and gestational age in 17 postmortem fetal specimens with this syndrome. Long-bone and crown-rump lengths were compared with normal regression lines and foot length was compared with gestational age determined on the basis of menstrual dates. Correlation between foot length and menstrual dates was weak in trisomy 18. Gestational age predicted by crown-rump length was significantly lower than gestational age by menstrual dates. All long bones were significantly shortened and fell below normal regression lines for gestational age. The fetal femur/foot length ratio was reduced. Thus no endogenous measure of gestational age appears to exist in this aneuploidy, forcing reliance on menstrual dates. The observed pattern of growth alterations will likely preclude the development of a gestational age–dependent biometric screen for the prenatal detection of this syndrome. (Am J Obstet Gynecol 1990;163:158-61.)

Key words: Trisomy 18, linear growth, bone length

Trisomy 18 is the second most common autosomal trisomy in man with an estimated incidence of 0.3/1000 live births.[1] Morphologic and pathologic findings of this syndrome in newborns have been extensively described,[2] but little is known about growth of affected fetuses. Intrauterine growth retardation and severe postnatal failure to thrive are thought to be common.[2, 3] Recently, altered growth of the limbs has received considerable attention as a potential sonographic screen for Down syndrome.[4, 5] Similar information on limb length in fetuses with trisomy 18 is not available. We report on linear growth of the crown-rump length, the foot, and the long bones of the upper and lower extremities in postmortem second- and third-trimester fetuses with this syndrome.

Material and methods

The methods for collection and postmortem examination of fetal specimens in the Central Laboratory for Human Embryology have been previously published.[6]

Control fetuses were selected at random from a group of fetal specimens that resulted from either spontaneous or elective abortions. The karyotype was unavailable on these fetuses, but a detailed fetal autopsy did not disclose abnormalities. The prevalence of aneuploidy should be quite low in this group.[7]

Long-bone measurements were taken from a roentgenogram of the fetal limbs or were obtained by direct measurement after digestion of soft tissues in 5% or 10% potassium hydroxide. We have previously shown close correlation of roentgenogram and digestion techniques with minimal distortion.[8] Measurements obtained by digestion were converted to their roentgenogram equivalent by way of a regression equation. The control specimens were dated by foot length, which has been shown to be an accurate measure of gestational age in normal fetuses.[9] Long-bone lengths were plotted against gestational age by foot length, and appropriate linear regression equations were calculated. The normal bone lengths predicted by our regression equations fell well within the normal ranges of published long-bone growth curves as measured by ultrasonography.[10] The second-trimester control specimens were grouped by gestational week, and means and SDs were calculated for length of the long bones. These techniques with the applicable regression equations and normal ranges have been previously described in detail.[8]

The records of the Central Laboratory for Human Embryology were reviewed and nine second- and eight third-trimester fetuses with the trisomy 18 karyotype were identified. Limited information was available on one additional specimen that had been examined at an outside hospital. Some fetuses were studied immediately after termination of pregnancy, whereas others

¶Crown-rump length exceeds normal curve.

had been stored in 10% formalin since autopsy. Long-bone measurements were obtained by the roentgenogram technqiue.

Gestational age by last menstrual period was compared with gestational age according to the fetal foot length. The individual bone lengths of trisomic fetuses were compared with the normal regression lines for that bone. Whereas the gestational age in the 174 control fetuses had been assigned by foot length, menstrual dates were used to plot the trisomy 18 specimens. For the second-trimester trisomic specimens, bone lengths were also compared with the normal means for each gestational week. Too few normal third-trimester specimens were available to allow similar comparisons for specimens at older gestational ages.

Gestational age predicted by sitting crown-rump length according to the normal regression line in use at the Central Laboratory for Human Embryology[11] was compared with the gestational age of the specimen according to the last menstrual period. Finally, the femur/foot length ratios were calculated for the trisomic specimens.

Statistical analysis was by way of the one-sample or two-tailed paired Student *t* test for parametric data and the sign test for nonparametric data.

Results

Fetal foot length had been measured in 16 of our 17 specimens and the additional specimen from an outside institution. In the trisomic fetuses, a relatively poor correlation ($R^2 = 0.52$) was found for foot length and menstrual dates with gestational age by dates universally exceeding gestational age calculated from the fetal foot length (Table I). This difference was statistically significant ($p < 0.02$, Student paired *t* test). Therefore all trisomic specimens were dated according to the last menstrual period.

After 18 weeks' gestation the gestational age predicted by the sitting crown-rump length of the trisomic specimens was consistently less than the gestational age calculated from the last menstrual period (sign test; $p = 0.0012$; Table I).

All long-bone lengths in fetuses with trisomy 18 fell below the normal regression line for that bone. This observation is highly statistically significant (sign test; $p < 0.001$ for the lower extremity long bones, $p < 0.005$ for the upper extremity long bones). When compared with expected bone lengths calculated from the regression equations, upper and lower extremity bones of fetuses with trisomy 18 were significantly shorter (Student paired *t* test; $p < 0.002$; Table II).

In the nine second-trimester fetuses with trisomy 18, the long bones of the lower extremity were generally >2 SDs shorter than the normal mean for gestational age. Only two of nine femur lengths did not adhere to this pattern. In the upper extremity, long-bone shortening was less consistent with two of eight humeri, two of seven ulnas, and three of seven radii, measuring

Bone lengths are expressed in millimeters as mean ± 2 SD.

within 2 SDs of the normal mean for gestational age (Table III).

The mean femur/foot length ratio for the trisomic specimens was 0.714 ± 0.076 (range, 0.604 to 0.904), which falls significantly below the accepted normal range of 0.99 ± 0.06[12] during the second and third trimester (one-sample t test, $p < 0.001$).

Comment

Growth retardation is a recognized component of the trisomy 18 syndrome. Birth weights of affected fetuses and term or near-term neonates almost universally fall well below population means.[2, 3, 13, 14] Until recently, reduced growth of the crown-rump length and shortening of the long bones had been noted only in case reports.[15, 16] Lynch and Berkowitz[17] have now confirmed the early growth delay in this syndrome by sonographically showing crown-rump lengths that are smaller than expected in five first-trimester fetuses with trisomy 18. To date, however, second-and third-trimester linear growth in this second most common autosomal trisomy had not been studied systematically.

Our findings indicate that the upper and lower extremities in fetuses with trisomy 18 are significantly shortened. This deficiency in growth begins before week 18 of gestation and growth remains subnormal through the remainder of fetal development. Our data suggest that the lower extremity is more consistently affected than the upper limb. This finding is in contrast to our previous report of disproportionately reduced

growth of the upper extremity in Down syndrome.[8] In trisomy 18 growth of the lower limb thus appears to be less closely channelled than upper extremity development, which might also explain the lower extremity limb reduction abnormalities that have been noted by other authors.[18] In addition, we confirm the truncal growth delay noted by Lynch and Berkowitz, although in our series this did not become a consistent finding until after 18 weeks' gestation.

Fetal foot length is generally thought to be a reliable indicator of gestational age, making reliance on subjective recall of the last menstrual period unnecessary and adding valuable confirmatory information when other parameters do not accurately predict gestational age.[19] However, in trisomy 18, we have shown a poor correlation between foot length and gestational age by menstrual dates. This indicates that the profound growth deficiency that affects the lower extremity also affects growth of the foot, although growth of the foot appears to be better preserved than growth of the femur as suggested by the abnormally low femur/foot length ratios. A similar abnormality has been observed for the biparietal diameter/femur length ratio.[20] Because biparietal diameter and abdominal circumference also have reduced rates of growth in this syndrome,[21] our findings of universally slowed linear growth in fetuses with trisomy 18 supports the concept of an overall reduced potential for growth in this aneuploid condition.

The fact that the fetus with trisomy 18 lacks a reliable endogenous measure of gestational age is of clinical significance because a dependable sonographic screen would be highly desirable for a condition that has such serious implications for perinatal management and pregnancy outcome.[15] The utility and predictive value of such a sonographic screen for Down syndrome remain controversial.[5, 22] Unfortunately the data suggest that the symmetry of the observed growth deficiency, and the apparent lack of an endogenous predictor of gestational age in trisomy 18 will likely preclude the development of a gestational age–dependent biometric screen such as the "observed/expected" ratios that have been proposed for Down syndrome screening. Whether a parameter that is independent of gestational age, such as the femur/foot length or biparietal diameter/femur length ratio, will prove to be sufficiently specific to be of diagnostic use deserves further prospective study.

Recurrent adverse pregnancy outcome and antiphospholipid antibodies

E. Albert Reece, MD, Sandro Gabrielli, MD, Mark T. Cullen, MD, Xue-Zhong Zheng, MD, John C. Hobbins, MD, and E. Nigel Harris, MPhil, MD, DM

New Haven, Connecticut, and Louisville, Kentucky

Antiphospholipid antibodies, which include lupus-like anticoagulant and anticardiolipin antibody, have been linked to a number of adverse pregnancy outcomes, although their exact pathogenic mechanisms remain poorly defined. The relative risk of complications such as intrauterine growth retardation, spontaneous abortions, and stillbirth in patients with antiphospholipid antibodies also remains undetermined. Heightened attention has been focused on the association, leading to investigations into the pathogenesis. Uncontrolled studies have also explored therapeutic regimens such as aspirin, steroids, and heparin, and clinical trials have used various treatment protocols. Although knowledge into the association of antiphospholipid antibodies and recurrent adverse pregnancy outcome is limited and continues to evolve, this association provides new insights into the disease and offers promise for pharmacologic prophylaxis. In this article, current concepts on pathogenesis, diagnosis, and therapy are reviewed and recommendations are made for clinical care of these patients. (Am J Obstet Gynecol 1990;163:162-9.)

Key words: Antiphospholipid antibodies, spontaneous abortion, stillbirth, anticardiolipin antibody

Early fetal loss may be a result of a variety of causes including chromosomal abnormalities; however, the etiologic factors involved with many of these losses are unknown and are categorized as idiopathic.[1] Various investigators have shown an association between spontaneous abortion, intrauterine growth retardation, stillbirth, and the presence of antiphospholipid antibodies such as lupus-like anticoagulants and anticardiolipin antibody.[2-19] Some studies[2-5, 15, 16] have shown that elevated levels of anticardiolipin antibody (immunoglobulin G [IgG]) are associated with thrombosis and fetal loss. It is these factors, their mechanisms and processes, that have increasingly become a major focus of attention for the treatment of patients with unexplained reproductive failure or adverse pregnancy outcome.

The purpose of this article is to examine the strength of the association between poor pregnancy outcome and antiphospholipid antibodies, to review the current diagnostic methods, and to examine various therapeutic trials to provide recommendations for clinical care.

Antiphospholipid antibody and pregnancy outcome

Lupus-like anticoagulant is an immunoglobulin of the IgG or immunoglobulin M (IgM) class with anticoagulant activity considered to result from its interference with the activation of the prothrombin activator complex (prothrombin, factors Xa and V, calcium), probably by inhibiting the interaction of the above-mentioned factors and phospholipids (Fig. 1).[18, 19] Patients with the lupus-like anticoagulant or anticardiolipin antibody usually do not have bleeding diatheses, but rather, exhibit a tendency toward thrombosis.[20-24]

Laurell and Nilsson[25] first suspected a relationship between lupus-like anticoagulant and biologic false-positive serologic test for syphilis and showed that the Kahn antigen (a venereal disease research laboratory–related antigen) was associated with lupus-like anticoagulant activity. However, it was Conley and Hartman[26] who first showed lupus-like anticoagulant in two patients with systemic lupus erythematosus associated with false-positive tests for syphilis. Whereas originally

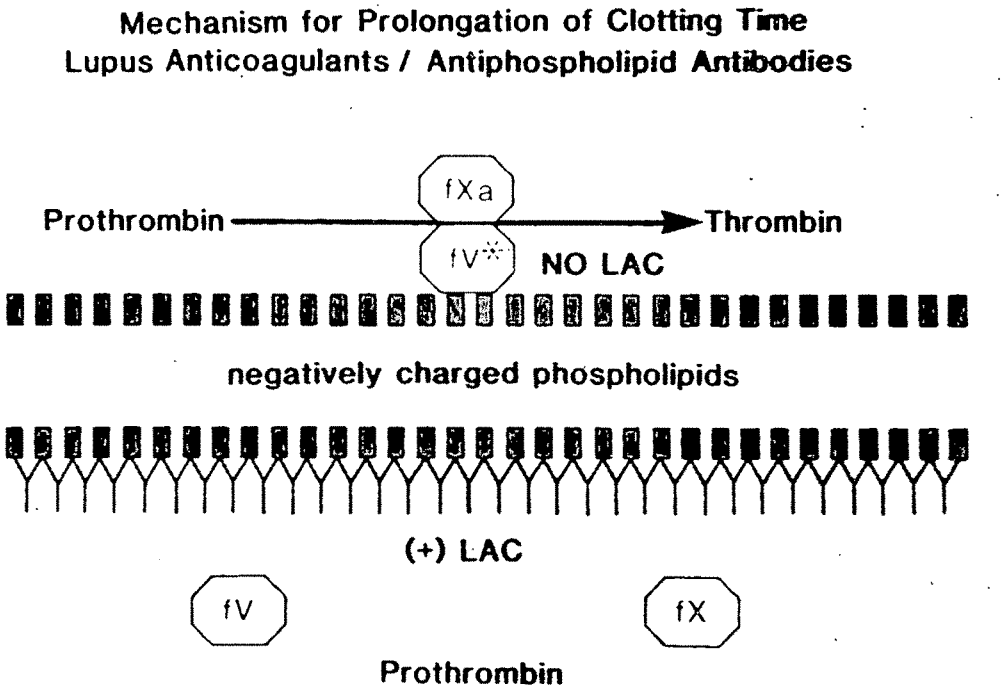

Fig. 1. Diagram of mechanism for lupus-like anticoagulant interfering with prothrombin complex.

detected in patients with systemic lupus erythematosus, the lupus-like anticoagulant has been subsequently found in association with other immunologic disorders and in patients with nonimmunologic diseases.[27]

Cardiolipin is the most active phospholipid in the venereal disease research laboratory assay systems. Antibodies responsible for lupus-like anticoagulant activity bind a variety of negatively charged phospholipids including cardiolipin,[18, 28-31] and this accounts for low-level false-positive venereal disease research laboratory test results in these patients. With the use of a solid-phase radioimmunoassay system to detect anticardiolipin antibody, Harris et al.[16, 30] showed these antibodies in a broad population of patients. More recently, reports have focused on the presence of antiphospholipid antibody, specifically the anticardiolipin antibody, in patients with subclinical autoimmune disease,[32] with systemic lupus erythematosus or with a history of recurrent abortion, thrombosis, or thrombocytopenia.[28, 32-39] Harris et al.[38] further emphasized that the anticardiolipin antibody (IgG subtype) level was predictive for fetal loss and thrombosis. The majority of patients with lupus-like anticoagulant, as identified by a functional coagulation assay, are also found to have anticardiolipin antibody, suggesting a strong link between the two groups of antibodies.[28] However, there are data to support that the anticardiolipin antibody is a better predictor of adverse pregnancy outcome than is the lupus-like anticoagulant.[40, 41] With the use of fetal death as the outcome variable, Lockshin et al.[40] reported a sensitivity for anticardiolipin of 0.85 and a specificity of 0.92.

It is estimated that about 20% to 30% of patients with systemic lupus erythematosus have an antibody to cardiolipin and are thereby at increased risk of vascular thrombosis in various organ systems. The biologic mechanism(s) by which thrombosis occurs is unknown. The inhibition of prostacyclin (PGI_2) production from endothelial tissues by fractions containing the antibody has been reported.[5, 21] This report was subsequently confirmed with aortic smooth muscle cell culture from rats.[21, 39, 42] The increased tendency toward thrombosis in patients with antiphospholipid antibodies may be a consequence of a number of factors including a decrease in fibrinolytic activity as a result of the inhibition of prekallikrein factor production,[43] acquired deficiency of proteins C and S, and antithrombin III activity.[44] Alternatively, inhibition of PGI_2 production by endothelial cells may be the common pathogenic mechanism leading to systemic thrombosis or the decidual vasculopathy observed in pathologic pregnancies.[21, 42] It also has been reported that the placentas of patients who experience adverse pregnancy outcome in the presence of antiphospholipid antibodies, particularly lupus-like anticoagulant, show extensive infarction.[42] Therefore, placental vasculopathy may be considered an expression of the generalized thrombotic process, resulting from an inhibition in the synthesis of prostacyclin, a natural antithrombotic agent.

Lockwood and colleagues[45] have examined the prev-

alence of lupus-like anticoagulant and anticardiolipin antibody in a low-risk population. This is of importance because the occurrence of normal outcomes in patients found to have high lupus-like anticoagulant or anticardiolipin antibody concentrations would discredit the role(s) of antiphospholipid antibodies in the pathogenesis of reproductive failure and adverse outcomes. In this study, which involved 737 sequential obstetric patients, Lockwood and colleagues[45] found that the presence of lupus-like anticoagulant in the general obstetric population was 2.7/1000, whereas the prevalence of anticardiolipin antibody was shown to be 22/1000. A number of patients were noted to have uncomplicated pregnancies despite the presence of antiphospholipid antibodies. However, increased levels of anticardiolipin antibody (IgG or IgM) resulted in higher incidences of adverse pregnancy outcomes.[45]

These data show that high titers of antiphospholipid antibodies do play a role in reproductive failure and adverse pregnancy outcome, although the precise mechanism remains undetermined. The occurrence of spontaneous abortions and the possible link to antiphospholipid antibodies may be underestimated because of the failure of patients to routinely seek prenatal care after an early pregnancy loss. The incidence of lupus-like anticoagulant as ascertained by a functional coagulation assay appears quite low in this population, but direct assay of the causative antibody (anticardiolipin antibody) reveals a prevalence of about 2% with affected patients. Such an association is significant inasmuch as a plausible explanation for certain adverse pregnancy outcomes was heretofore unknown.

Diagnosis

Clinical suspicion. The presence of antiphospholipid antibodies should be considered in cases of unexplained recurrent spontaneous abortions, intrauterine growth retardation, or stillbirth.[2-14] Indications for such investigation include a clinical suspicion of systemic lupus erythematosus, with or without associated venous or arterial thromboses by history; unexplained thrombocytopenia or hypoprothrombinemia; the presence of positive antinuclear antibodies, antismooth muscle antibodies or a false-positive venereal disease research laboratory test.[10, 46, 47] The confirmation of antiphospholipid antibodies can only be done through laboratory testing.

Laboratory diagnosis

Lupus-like anticoagulant. The lupus-like anticoagulant interacts with the phospholipid portion of the prothrombin activator complex. If plasma contains high levels of this immunoglobulin, the partial thromboplastin time (PTT) and occasionally the prothrombin time (PT) are prolonged. With the use of exponential dilutions of tissue thromboplastin, Boxer et al.[27] showed a more prolonged PT in patient plasma as opposed to control plasma at high dilutions of the tissue thromboplastin. However, there is evidence that the PTT is more sensitive than the PT, and in general, the PTT is the only abnormal hematologic parameter. This contrasts with the observed tendency toward thrombosis, which is thought to be mediated through platelet activation, an increase in thromboxane levels, and its impact on membrane phospholipid, causing a decrease in prostacyclin (Fig. 2). The test that is currently performed is the activated partial thromboplastin time (APTT) or the Russell viper venom time. Reece et al.[48] proposed a simple method for investigation of the cause of a prolonged APTT. If a patient has an unexplained prolonged APTT, normal plasma can be mixed with the patient's plasma, and if the APTT is corrected by this mixing of blood, a clotting factor deficiency should be suspected. If the APTT is not corrected, then the presence of circulating anticoagulants such as lupus-like anticoagulant should be considered. Lupus-like anticoagulant is confirmed if the APTT is corrected by addition of an increased amount of phospholipid[24] or by addition of freeze-dried platelets.[49] As mentioned previously, if no correction is observed, specific coagulation factor deficiency should be investigated (Fig. 3).

Anticardiolipin antibody. Anticardiolipin antibodies are demonstrated in patients' sera by solid-phase radioimmunoassay[28, 50] or, more recently, by enzyme-linked immunoassay tests.[46, 47] In brief, these methods involve coating wells of a plastic plate with cardiolipin then adding appropriately diluted patient's sera. If anticardiolipin antibody are present in the patient's sera, they will stick to the cardiolipin-coated wells, and their presence can be detected by the addition of radiolabeled antihuman antibodies or enzyme labeled antihuman antibodies. Since these tests were introduced, considerable improvements in their performance have occurred, and efforts are in progress for their standardization.[47, 51]

Other related tests. Antibodies to cardiolipin can give rise to biologic false-positive venereal disease research laboratory test results because the serologic tests also use phospholipid substrates. Antinuclear antibodies have been reported to occur in about 40% to 70% of patients with antiphospholipid antibodies. However, the original theory that nuclear and phospholipid epitopes are the same has been disproved.[16, 29, 30, 52] The presence of antidouble-stranded deoxyribonucleic acid (DNA) in the sera of patients with anticardiolipin antibody cannot be attributed to shared epitopes. Anti-DNA and antismooth muscle antibodies may also be present in patients with systemic lupus erythematosus. Similarly, lower titers of the C4 fraction of complement have also been reported in patients with systemic lupus

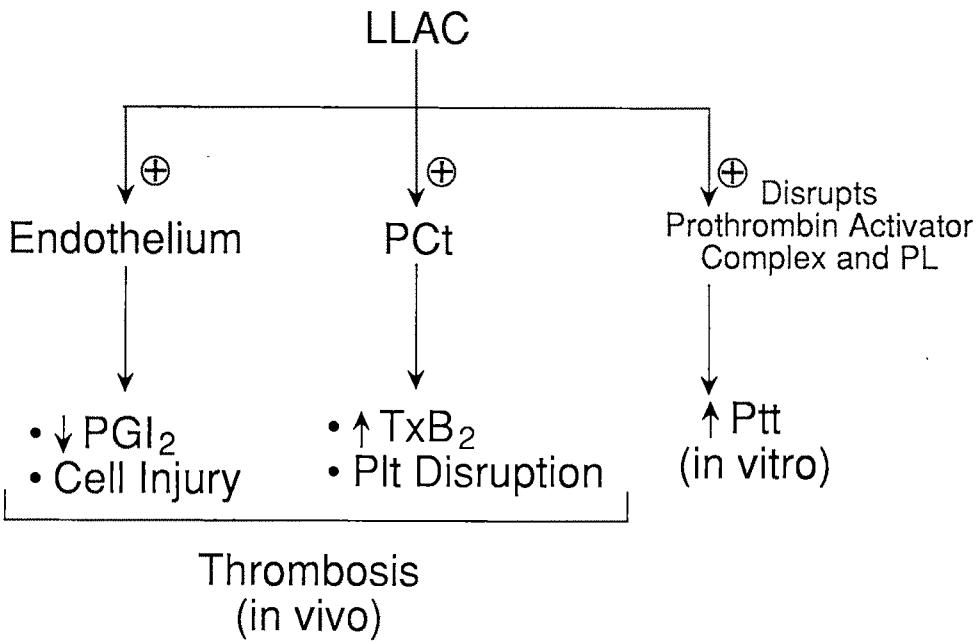

Fig. 2. Diagram of effect of lupus-like anticoagulant, which causes thrombosis in vivo and prolongation of partial thromboplastin time in vitro.

erythematosus and antiphospholipid antibodies.[53] In addition, there has been a suggestion that autoantibodies are associated with fetal loss, possibly through different mechanisms. For example, the anti-Ro may be through a congenital heart block mechanism and the anticardiolipin antibody may be through a placental ischemic mechanism.[54]

Treatment

There is no general agreement among investigators on the optimum treatment, if any, for high-risk patients with lupus-like anticoagulant or anticardiolipin antibody. In 1952 Conley and Hartman[26] used adrenocorticotropin hormone to obtain the disappearance of the lupus-like anticogulant. More recently, successful treatment protocols that use various combinations of high doses of corticosteroids and low-dose aspirin have been reported (Table I). The administration of corticosteroids suppressed the lupus-like anticoagulant as shown elsewhere.[26, 57, 65] Aspirin was added to counteract the increased tendency of platelets to aggregate and adhere, which may be responsible for the inclination toward thrombosis and adverse pregnancy outcomes.

In the literature to date there are several reports that chronicle the various therapeutic regimens (prednisone, aspirin, and heparin) and pregnancy outcome (Table I). The overall live birth rate with all forms of treatment was 66.9%. Further analysis revealed a live birth rate of 39% with steroid or azathioprine, 41.2% with steroid or azathioprine and heparin, and 79.1% with steroid or azathioprine plus aspirin.

Branch et al.,[8] with the use of a therapeutic protocol similar to that used by other investigators, found that a restoration to normal of the APTT did not ensure a live birth. Therefore, meticulous antepartum care was advised in view of the ever-present danger of preeclampsia, intrauterine growth retardation, and fetal death. With the use of high-dose corticosteroid and aspirin, Farquharson et al.[59] managed a patient who had a history of previous abortions and prolonged clotting time and in whom the mixing tests were consistent with the presence of lupus-like anticoagulant. The patient experienced a severe thrombosis of the right vertebral and posterior-inferior cerebellar arteries. The pregnancy was terminated. In light of this complication, the author suggested the initiation of therapy before conception. Controversy reigns, not only with regard to treatment regimens but as to whether or not to treat. Some investigators are reluctant to treat patients with high-dose corticosteroids and aspirin, citing the significant potential risk for maternal and fetal complications.[11, 12, 15]

In patients with both lupus-like anticoagulant and anticardiolipin antibody, a debate has ensued over which of the two groups of antibodies can be more easily suppressed with aspirin and corticosteroids and how this suppression, or the lack thereof, may relate to pregnancy outcome. Reports from various authors[15, 64, 66] showed that anticardiolipin antibody is more difficult to suppress but is a better prognostic indicator than lupus-like anticoagulant. However, Parke et al.[9] were able to achieve a good outcome after suppression

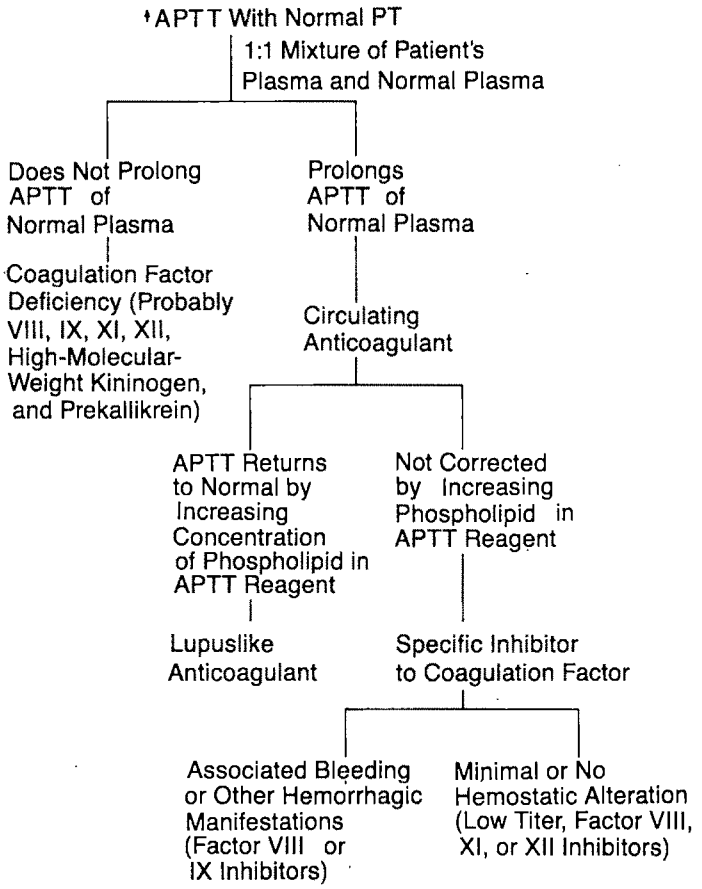

Fig. 3. Flow diagram depicts single method of evaluating patients with abnormal APTT, circulating anticoagulants, or factor deficiencies can be investigated by this means. (From Reece EA, Clyne LP, Romero R, Hobbins TC. Spontaneous factor XI inhibitors. Arch Intern Med 1984;144:525-9. Copyright 1984, American Medical Association. By permission.)

of anticardiolipin antibody in a patient with a history of five previous abortions. In this study high-dose corticosteroid was given before and throughout pregnancy. Serial measurements of anticardiolipin antibody and lupus-like anticoagulant antibodies were made and showed a continuous decline in anticardiolipin antibody concentrations, with the APTT eventually becoming normal. The dilute tissue thromboplastin inhibition test, chosen as a measure of the lupus-like anticoagulant, became prolonged when the patient became pregnant. At 27 weeks' gestation the patient had severe preeclampsia, necessitating premature delivery at 29 weeks' gestation. The neonate did not reveal anticardiolipin antibody in the peripheral blood, and the placenta was small with some infarcted areas.[9]

In another study by Norberg et al.,[59] the level of the APTT and/or anticardiolipin antibody concentration was shown not to be related to pregnancy outcome. The authors emphasized that high concentrations of anticardiolipin antibody may be transiently elevated also in patients with infectious diseases such as cytomegalovirus or human immunodeficiency virus infection. However, this association seems to be temporary and not significantly connected with any clinical or laboratory findings.

In our series (Unpublished data), live births occurred among 14 (77.8%) of our 18 patients with antiphospholipid antibodies and prior pregnancy losses treated with prednisone or low-dose aspirin during pregnancy. We also observed a unique association between the number of prior fetal losses, the anticardiolipin antibody titer, and the fetal survival rate after therapy. Two or more prior fetal losses and high autoantibody titer resulted in a fetal survival rate of 50% to 75% with varying therapeutic regimens and dosages. However, an improved fetal survival rate of 75% to 100% was observed with fewer than two prior fetal losses and low- to midanticardiolipin antibody titer with the same therapy.

As Table I shows, the treatment regimens used to date have employed various combinations of corticosteroid, heparin, and aspirin. In most cases, the outcome of the pregnancies improved with therapy. The optimum obstetric management and treatment remain unsettled. However, the latter is part of a large, ongoing multicenter clinical trial sponsored by the National In-

Table I. Treatment and pregnancy outcomes of pregnant patients with antiphospholipid antibodies and prior adverse outcomes

stitutes of Health in which we are engaged. In this study, low-risk patients (one or no losses and antiphospholipid antibodies) are randomized to usual care versus low-dose aspirin, and high-risk patients (two or more losses plus antiphospholipid antibodies) are randomized to aspirin plus heparin versus aspirin and prednisone.

Some investigators have suggested that antepartum fetal heart rate monitoring or Doppler ultrasonography may be useful in the identification of fetuses at risk of sudden death.[67, 68] The drawback in such reports includes the lack of a control population against which findings can be compared. However, from a practical standpoint, because these forms of tests are acceptable means of assessing fetal well-being, such are well advised for these at-risk patients.

Comment

In summary, reproductive failure and adverse pregnancy outcomes including recurrent abortions, intrauterine growth retardation and fetal death cannot always be explained. Recent evidence suggests that a small subset of patients with adverse pregnancy outcomes, previously categorized as idiopathic, may have high concentrations of antiphospholipid antibodies.

Cardiolipin is the primary epitope of the antiphospholipid antibody family, being present in many cases of unexplained recurrent adverse pregnancy outcomes. Assays for anticardiolipin antibody activity appear to be the optimal screening tool for identification of patients at risk of the aforementioned pregnancy outcomes. Therapeutic protocols based on aspirin, corticosteroids, or heparin have been successfully used.[69] However, because maternal and fetal complications have been reported in patients who receive such therapy, extreme caution must be exercised. The ad hoc use of treatment protocols, without appropriate consultation, should be discouraged until further studies are conducted to elucidate the optimum therapeutic regimens, dosages, timing, and duration of therapy.

We thank Dr. Charles Lockwood, Lionel Clyne, Nancy DeGennaro, and Lisa Cabral for their assistance in the preparation of this manuscript.

The effect of adrenocorticotropic hormone infusion on subsequent pituitary response in the sheep fetus

William V. Cuthrell, MD,[a] James C. Rose, PhD,[a, b] and Paul J. Meis, MD[a]
Winston-Salem, North Carolina

It is not known whether activation of the fetal adrenal gland can inhibit pituitary adrenal responses to stress. Therefore we treated 14 chronically cannulated sheep fetuses (gestational age range, 109 to 129 days) with an adrenocorticotropic hormone infusion of 5 ng/kg per minute or vehicle solution at similar rates for 2.5 hours and then subjected them to a 10-minute period of hypotension. Resting mean arterial blood pressures were similar for both control and adrenocorticotropic hormone infusion groups and decreased similarly after administration of sodium nitroprusside. Resting fetal plasma cortisol levels (11.6 ± 3.3 ng/ml) and adrenocorticotropic hormone (42 ± 15 pg/ml) concentrations were not different in the two groups. In the control group fetal plasma cortisol concentrations rose from 12.1 ± 1.7 to 35.7 ± 8.0 ng/ml after hypotension ($p < 0.05$) and plasma adrenocorticotropic hormone increased from 37 ± 19 to 145 ± 67 pg/ml ($p < 0.05$). In the group treated with adrenocorticotropic hormone, fetal plasma cortisol concentrations increased (30.2 ± 7.8 to 53.6 ± 15.0 ng/ml; $p < 0.05$) after hypotension whereas fetal plasma adrenocorticotropic hormone concentrations did not increase (398 ± 227 versus 258 ± 77 pg/ml; $p > 0.05$). (Am J Obstet Gynecol 1990;163:170-4.)

Key words: Pituitary-adrenal axis, adrenocorticotropic hormone, stress

The ontogeny of pituitary development in the sheep fetus has been examined by studying the response of the fetus to hypoxemia and hypotensive stress induced by hemorrhage, and more recently to hypotension induced by sodium nitroprusside (Nipride).[1, 2] Studies have shown that there is earlier development of the adrenocorticotropic hormone (ACTH) response to stress with accompanying cortisol response occurring later in gestation.[3] The existence of a feedback relationship has been studied by the administration of exogenous cortisol and examination of its effect on the subsequent pituitary-adrenal response to stress.[4] This relationship has also been examined by stimulation of the pituitary gland with corticotropin-releasing factor after cortisol infusion at varying gestational ages.[5] Until this time the exogenously administered cortisol has been assumed to be of a physiologic amount on the basis of basal cortisol levels. Because cortisol production by the fetus is thought to be minimal until after 121 days[6] and yet there is ACTH responsiveness much earlier[7] this study was conducted to assess whether the sheep fetus at 109 to 129 days' gestation can increase endogenous cortisol levels sufficiently to exert negative feedback effects on stress-stimulated ACTH production.

Material and methods

A total of 24 fetal lambs were surgically instrumented at a gestational age between 109 and 128 days. Polyvinyl catheters were placed in the fetal and maternal inferior vena cava and distal abdominal aorta via femoral vessels.

Fetal status was monitored with arterial blood gas evaluation intraoperatively and on a periodic basis postoperatively. The animals were allowed to stabilize 3 to 5 days before study. The experimental protocol consisted of a 2.5 hour ACTH infusion at 5 ng/kg per minute for a total volume of 20 ml or a control infusion of 0.1% bovine serum albumin in saline solution. Before the infusion the ewes and fetuses were allowed to stabilize for 40 minutes after being connected to the hemodynamic monitoring equipment. Fetal arterial blood pressure, heart rate, and amniotic fluid pressure

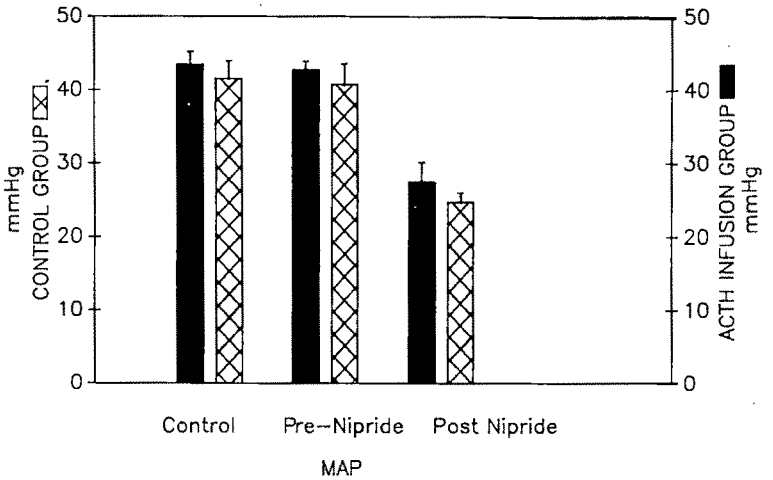

Fig. 1. Fetal mean arterial blood pressure during experiment.

were monitored continuously during the experiments. Samples were taken at periodic intervals from the fetus for cortisol, ACTH, arterial blood gas, and hematocrit evaluations. The sample volume was 2.5 ml whole blood and the sample volume was replaced with an equivalent volume of saline solution to maintain euvolemia. Cortisol and ACTH samples were collected in tubes that contained ethylenediaminetetraacetic acid and were immediately placed on ice. The samples were then centrifuged. The plasma was collected and frozen at −20° C until assay. At the completion of the ACTH or control infusion, an infusion of control solution was started or continued for an additional 30 minutes before hypotension was induced by sodium nitroprusside. Then an infusion of sodium nitroprusside was begun at a rate sufficient to lower the fetal mean arterial blood pressure by approximately 40%. This infusion was continued for a total of 10 minutes at which time the final samples for ACTH, cortisol, hematocrit, and arterial blood gas evaluation were taken and the infusion was stopped.

Plasma cortisol concentrations were measured with a previously described radioimmunoassay.[2] Plasma ACTH levels were analyzed in unextracted plasma by radioimmunoassay with commercially available reagents (Immunonuclear).

Blood pH, P_{O_2}, and P_{CO_2} were measured with a blood gas analyzer (model ABL 30, Radiometer, Copenhagen, Denmark.)

All fetal blood pressures were calculated with amniotic fluid pressure as a zero reference. Pressures and heart rate were sampled by microcomputer and an appropriate analog to digital converter and were averaged for 60-second intervals except during the sodium nitroprusside infusion when samples were averaged at 30-second intervals. A continuous strip chart recording of the same parameters was also maintained during the experiment. Fetal plasma cortisol and ACTH levels were compared immediately before and after the sodium nitroprusside infusion. Because of sample inhomogeneity of variance, the Wilcoxon paired sample test was used to statistically analyze the results. Similar time interval comparisons were made of blood pressure, pH, P_{O_2}, P_{CO_2}, and maternal cortisol values. Statistical analyses of these parameters were by analysis of variance.

Results

Initially 24 animals were studied with 12 in each group, ACTH or control. After examination of fetal blood gas data, five animals were eliminated from each group because of blood gas values that indicated acidosis, hypoxemia, or hypercapnia (pH <7.2, P_{O_2} <15 mm Hg, P_{CO_2} >55 mm Hg).

Analysis of the hemodynamic variables of the remaining animals did not reveal statistically significant differences in fetal mean arterial blood pressures or heart rate over the course of the ACTH or control saline solution infusions. During the infusions of sodium nitroprusside there were similar reductions in mean arterial blood pressure. In the ACTH group blood pressure declined 15 ± 2 mm Hg (36%) and in the control group 16 ± 2 mm Hg (38%). These were not statistically different (Fig. 1).

Blood gas values from the fetuses after elimination of the abnormal animals were not different between groups (Table I).

Statistical analysis of the cortisol concentrations from each group showed a significant rise over the course of hypotension induced by sodium nitroprusside. The fetal plasma cortisol levels in the ACTH group rose from 30.2 to 53.5 ng/ml ($p < 0.05$) and in the control group the fetal plasma cortisol levels rose from 21.1 to 35.6 ng/ml ($p < 0.05$). The ACTH group showed a rise in fetal plasma cortisol levels over the course of the

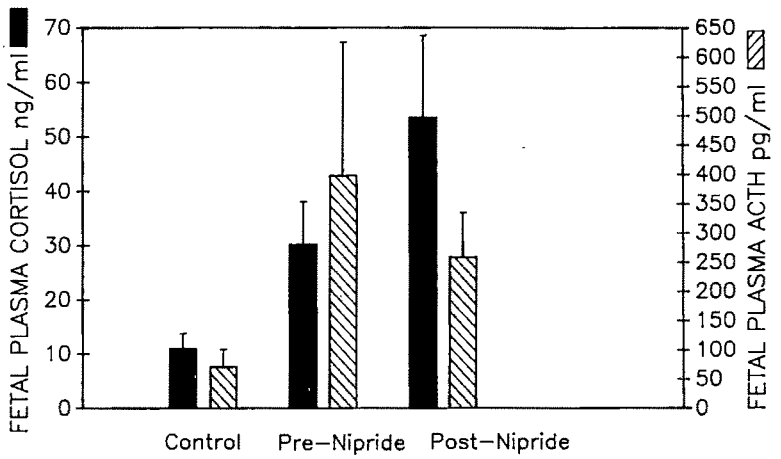

Fig. 2. Fetal plasma cortisol and ACTH levels during experiment in ACTH infusion group ($n = 7$).

Table I. Fetal blood gas data during experiment

	Control group ($n = 7$)			*ACTH infusion group ($n = 7$)*		
	Control	*Before sodium nitroprusside*	*After sodium nitroprusside*	*Control*	*Before sodium nitroprusside*	*After sodium nitroprusside*
pH	7.34 ± 0.01	7.33 ± 0.02	7.32 ± 0.04	7.34 ± 0.01	7.32 ± 0.01	7.31 ± 0.01
P_{O_2} mm Hg	20.8 ± 0.8	21.2 ± 0.8	23.1 ± 1.4	18.9 ± 1.0	17.9 ± 1.1	20.6 ± 0.9
P_{CO_2} mm Hg	44.4 ± 1.5	43.1 ± 2.7	45.1 ± 3.7	48.0 ± 1.2	47.8 ± 2.0	49.4 ± 2.1

ACTH infusion. No consistent change was found in fetal plasma cortisol concentration during the saline solution–bovine serum albumin infusion in the control group. The fetal plasma ACTH concentration in the control group showed no change until after hypotension was induced by sodium nitroprusside and then rose from 37 ± 19 to 145 ± 67 pg/ml ($p < 0.05$). In contrast, plasma ACTH concentration in the ACTH infusion group showed no significant change after hypotension was induced by sodium nitroprusside (Figs. 2 and 3).

Comment

Multiple investigators have examined the developmental aspects of the pituitary-adrenal axis. Sheep fetuses at varying gestational ages were subjected to hypotensive stress and the effect on ACTH and vasopressin were examined. These studies showed an ACTH response as early as 95 days' gestation but attenuated cortisol response until 109 days' gestation.[2] In the group >123 days' gestation basal ACTH concentrations were lower but cortisol levels were higher. Other studies have shown that ACTH production in response to corticotropin-releasing factor exists as early as 95 days' gestation but cortisol production remains modest until 125 days' gestation.[5,7] In these studies basal cortisol levels were higher at 135 days' gestation with decreased ACTH responses to stimulation by corticotropin-releasing factor. Before that gestational age it is uncertain whether the fetus can respond to ACTH stimulation with sufficient cortisol production to cause feedback on ACTH production.

Specific effects of increased cortisol levels on fetal stress responses have been shown by the administration of cortisol to sheep fetuses in physiologic amounts. Studies have shown that cortisol infusions to sheep fetuses between 94 and 131 days' gestation diminished ACTH responses to hypotensive stress.[4,8] Glucocorticoid suppression of the fetal ACTH response to corticotropin-releasing factor or arginine vasopressin administration has also been shown in the sheep fetus by 113 days' gestation.[9-11]

Results in this study are consistent with those cited in that ACTH-induced cortisol secretion is shown over a gestational range of 109 to 129 days. ACTH responsiveness to hypotensive stress is similarly shown. Furthermore, this study illustrates that ACTH administration can increase fetal plasma cortisol levels sufficiently to attenuate an ACTH response to stress. An argument could be made that the ACTH levels achieved during stress induced by sodium nitroprusside represents a maximal output of ACTH by an immature pituitary as opposed to decreased ACTH production as a result of cortisol feedback on the pituitary gland. Recent studies investigating the decreasing sensitivity of the pituitary gland to negative feedback in gestations close to term

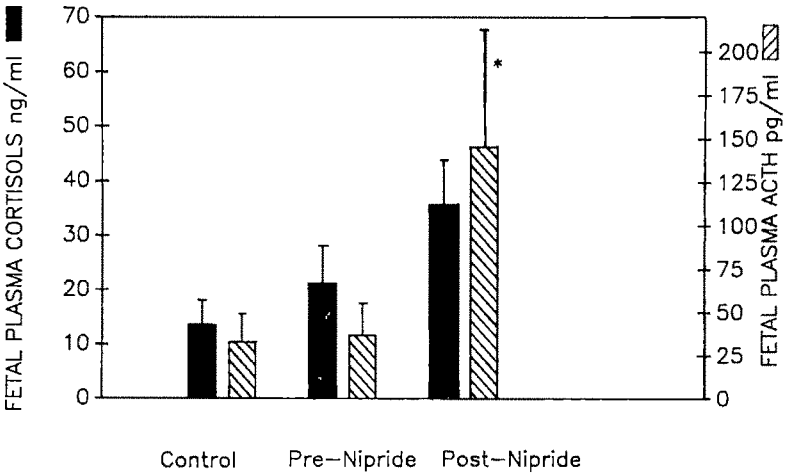

Fig. 3. Fetal plasma cortisol and ACTH levels during experiment in control group ($n = 7$). *Asterisk* indicates statistical significance.

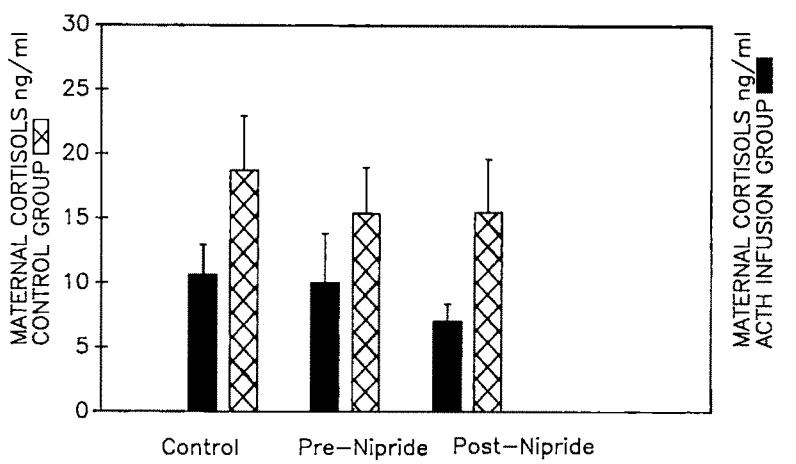

Fig. 4. Maternal plasma cortisol levels during experiment.

have shown that ACTH production in sheep can surpass 1000 pg/ml in response to hypotension induced by sodium nitroprusside.[12] Therefore it is believed that the ACTH levels in response to stress in this study represent submaximal production as a result of feedback inhibition. Other studies have similarly shown high ACTH levels in response to hypoxemia.[1]

Unexpectedly, the fetal cortisol response to stress was not attenuated by ACTH pretreatment. Several studies have shown that with pituitary-adrenal maturation occurring after 110 days of gestation there are two changes that affect ACTH and cortisol production. Stimulation of corticotropin-releasing factor produces less of an ACTH response as the fetus approaches term. However, adrenal responsiveness to ACTH increases such that there is a higher basal level of cortisol, resulting in increased negative feedback on ACTH production.[3, 7] In vivo and in vitro studies have shown that prolonged stimulation of the fetal adrenal by ACTH administration results in priming of the fetal adrenal and that further stimulation of the adrenal either in vivo or in vitro with dispersed pretreated adrenal cells produces greater cortisol production.[5, 13-15] Such a priming effect may have influenced cortisol levels in these experiments.

Because of the known contribution of maternal cortisol to the fetal cortisol level in early gestation the cortisol levels in the ewe were monitored during the course of the experiment. It is known that until 121 days' gestation maternal cortisol contributes a large proportion to the fetal cortisol level by placental transfer.[6] Thus high maternal levels could alter the fetal levels and exert negative feedback on the fetal adrenal gland. In this study the maternal cortisol levels did not show a trend in either group during the course of the experiment although they were higher in the control

study animals. Even with somewhat higher maternal cortisol levels the group of control animals showed the expected ACTH response to stress and therefore the maternal levels had no detectable effect on the control group (Fig. 4).

Another explanation for the presence of an increase in cortisol levels without an increase in ACTH can be found in the fact that some studies have shown that peptides other than ACTH may stimulate the fetal adrenal gland. Studies have shown that a rise in cortisol concentration occurs after the administration of melanocyte-stimulating hormone to newborn lambs.[16] Recent studies have also shown immunoreactive ACTH does not necessarily include the total amount of bioactive ACTH, although the difference is more pronounced in early gestation than at term.[17]

Finally, the time course of any ACTH response, and to a lesser extent cortisol response, may have been altered by the ACTH infusion so that sample timing after the infusion of sodium nitroprusside may not coincide with an increase in the plasma ACTH level. If that were the case, sampling at the end of the sodium nitroprusside infusion could possibly miss detection of an acute ACTH response that occurred at the onset of the hypotension induced by sodium nitroprusside. This seems unlikely because studies in adult dogs in which the pituitary-adrenal axis was stimulated with ACTH and then stressed with hypoglycemia showed that the subsequent ACTH response was both blunted and delayed such that the sampling at 10 minutes of stress detected the ACTH response.[18]

In summary, this study shows that at 109 to 129 days' gestation in the sheep fetus cortisol levels are modest and can be increased by ACTH. This increase in cortisol concentration is sufficient to modify the pituitary response to hypotensive stress by a negative feedback relationship. This study is in agreement with previous studies that show decreased ACTH production in response to stress or corticotropin-releasing factor when circulating fetal cortisol levels are increased by cortisol infusion.

Changes in platelet angiotensin II binding sites associated with the human menstrual cycle

Philip N. Baker, BM, Fiona Broughton Pipkin, DPhil, and E. Malcolm Symonds, MD
Nottingham, England

We have shown a significant decrease in platelet angiotensin II binding site concentration associated with the luteal phase of the menstrual cycle ($p < 0.02$). (AM J OBSTET GYNECOL 1990;163:175-6.)

Key words: Angiotensin II, platelet membrane glycoproteins, renin-angiotensin system

Human platelet angiotensin II receptors have been found to respond to sodium intake–induced changes in plasma angiotensin II concentration in a similar manner to that of receptors in arterial muscle.[1] Increased platelet angiotensin II binding in human pregnancy has been reported,[2] and we have noted that these pregnancy-induced changes commence in the first few weeks of pregnancy (Unpublished observations). The purpose of this study was to determine whether the menstrual cycle was associated with alterations in platelet angiotensin II binding site levels.

On two occasions 40 ml of venous blood was taken from 15 women (aged 20 to 42 years; median, 25 years). The first sample was taken between days 5 to 9 of the menstrual cycle and the second sample was obtained on day 21. All the subjects were normotensive, gave a history of regular cycles, and were not taking medication or oral contraceptives. Approximately 20 ml of blood was used to determine platelet angiotensin II binding, as previously described.[1] Serum urea and electrolytes, angiotensin II, renin substrate, renin concentration, and progesterone estimations were performed with the remaining blood.

A rise in serum progesterone level from <5 nmol/L at days 5 to 9 to >30 nmol/L at day 21 was adjudged to indicate ovulation.

Fig. 1 summarizes the changes in platelet angiotensin II binding sites. In the ovulatory patients there was a significant fall in binding site concentration ($p < 0.02$, Wilcoxon nonparametric paired test) from a median value of 11.2 fmol/10^9 cells at days 5 to 9 to a median value of 3.6 fmol/10^9 cells at day 21. There was also a significant rise in both the median values of plasma angiotensin II (from 9.4 to 16.5 pg/ml, $p < 0.05$), and in median values of plasma renin concentration (from 1.6 to 4.9 μmol, $p < 0.05$). The rise in plasma renin substrate was not statistically significant.

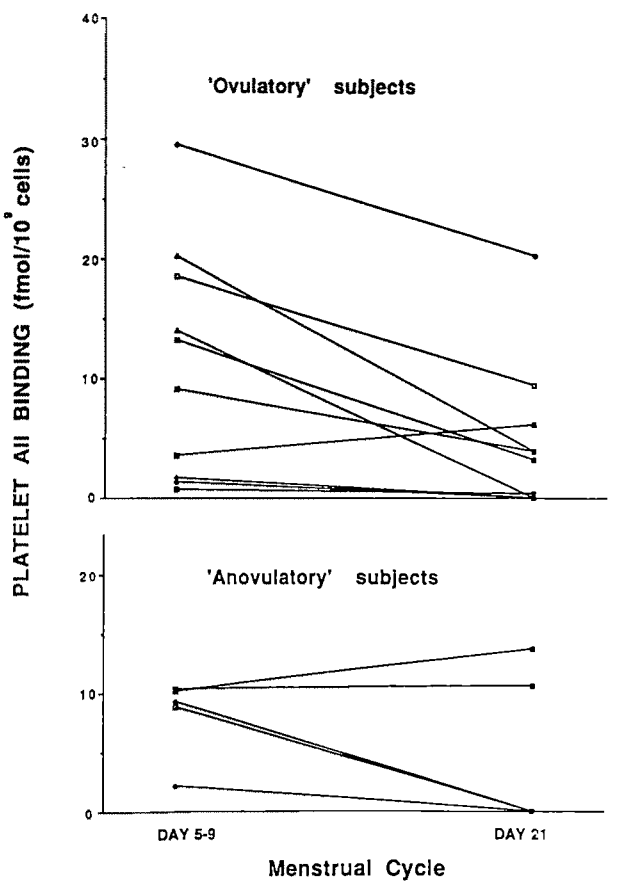

Fig. 1. Platelet angiotensin II binding site concentration in human menstrual cycle.

An increase in binding site concentrations was found

in two of the five patients deemed to be anovulatory. Despite the small numbers, a significant difference in the change in plasma angiotensin II was shown in these patients as compared with the ovulatory patients, with the median value of plasma angiotensin II falling from 29.0 to 15.6 pg/ml ($p < 0.05$, Mann-Whitney U test).

Thus this study suggests that the elevated levels of the components of the renin-angiotensin system in the normal menstrual cycle are accompanied by reduced levels of angiotensin II binding sites on platelets (a suggested model of vascular smooth muscle[1,2]).

Preventing cervical conization by achieving satisfactory colposcopy with hygroscopic cervical dilators

Jeffrey L. Stern, MD,[a] Carol Major, MD,[a] and Linda Van Le, MD[b]
San Francisco, California, and Milwaukee, Wisconsin

Eighteen women with abnormal cervical cytologic findings and unsatisfactory colposcopic examinations underwent cervical dilatation with Dilapan (Gynotech), a hygroscopic dilator. Dilatation exposed the entire squamocolumnar junction, converting an unsatisfactory colposcopic examination into a satisfactory one and avoiding cervical conization in 17 of the patients. (Am J Obstet Gynecol 1990;163:176-7.)

Key words: Dilapan, unsatisfactory colposcopy, cone biopsy

Since the advent of colposcopy, the frequency of cone biopsy for the evaluation of cervical cancer and intraepithelial neoplasia has decreased significantly. Nonetheless, a significant number of cone biopsies are performed each year in the United States because of unsatisfactory colposcopy. Colposcopy is considered unsatisfactory if the entire transformation zone or each of the areas of atypical cervical epithelium cannot be completely visualized. Unsatisfactory colposcopy occurs in an estimated 10% to 15% of all women less than 45 years of age with abnormal cervical cytology and occurs even more frequently in postmenopausal women.[1] In these individuals a cervical conization is performed for histologic diagnosis; as a result, one in six women with cervical dysplasia will require a cone biopsy. A cone biopsy may result in an incompetent cervix in pregnancy and an increased risk of premature labor. Subsequent cervical evaluations may be hampered secondary to ascension of the squamocolumnar junction into the endocervical canal. Other problems include bleeding, infection, anesthesia risks, and cost.

We report the results of a simple technique: dilatating the cervix with Dilapan (Gynotech, Salem Industrial Park, Lebanon, N.J.), a hygroscopic cervical dilator, to convert unsatisfactory colposcopy into a satisfactory colposcopic examination.

Material and methods

Eighteen consecutive premenopausal women undergoing colposcopic evaluation under the supervision of the senior author for an abnormal Papanicolau smear had unsatisfactory colposcopic examinations even after using an endocervical speculum. The patients were premedicated with oral prostaglandin synthetase inhibitors and the cervix was prepped. One Dilapan cervical dilator was inserted just past the external os without penetrating the internal os. The dilator was left in place for 1 to 2 hours. Patients either waited in the waiting room or left the office to return at a designated time. After removal of the dilator with a ring forceps, colposcopic evaluation was repeated.

Results

The entire transformation zone was visualized in 17 of 18 patients undergoing cervical dilation. Cramping

From the Department of Obstetrics, Gynecology and Reproductive Sciences, University of California at San Francisco,[a] and the Department of Obstetrics and Gynecology, University Physicians Milwaukee Clinical Campus Practice Plan, Milwaukee.[b]

was minimal and no significant complications, including infection, occurred. Early in the study, one Dilapan cervical dilator broke off in the cervical canal during removal. The fragments were easily removed with a packing forceps.

Comment

Dilapan is a hema polymer dilator with hydrophilic properties similar to traditional laminaria japonica; however, it expands more rapidly. It may be used in clinical settings suitable for traditional laminaria and may be preferred due to its rapid action.[2] The Dilapan we used measured 3 mm in diameter and 25 mm in length. When exposed to physiologic saline solution or cervical mucus, its diameter quickly increases from 3 to 8 to 10 mm. Previous use of Dilapan has not resulted in significant morbidity, and its efficacy at cervical dilatation has been documented in early pregnancy terminations.[2] Insertion of one Dilapan cervical dilator at a cost of $6 resulted in enough dilation to convert a colposcopic examination that was unsatisfactory even with an endocervical speculum into a satisfactory examination. The patients were comfortable and the examination could be completed in a short time. Within 2 hours a definitive diagnosis and recommendations for further therapy can be made; standard laminaria, on the other hand, take approximately 6 hours to fully expand.

We recommend this simple procedure in the evaluation of women with abnormal cytology and unsatisfactory colposcopy despite using an endocervical speculum.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1990 issues from the Publisher, at a cost of $56.00 ($79.00 international) for Vol. 162 (January-June) and Vol. 163 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318, USA; phone (800) 325-4177, ext. 7351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Sharing of human leukocyte antigens in primary and secondary recurrent spontaneous abortions

Hong-Nerng Ho, MD, Thomas J. Gill III, MD, Rhong-Phong Nsieh, BS, Hon-Jou Hsieh, MD, and Tzu-Yao Lee, MD

Taipei, Taiwan, and Pittsburgh, Pennsylvania

The prevalence of recurrent fetal loss and its relationship to sharing of human leukocyte antigens within couples was examined in a large, ethnically homogeneous Chinese population in Taiwan: 91 couples with primary recurrent spontaneous abortion, 32 couples with secondary recurrent spontaneous abortion, and 51 normal fertile couples. There was an excess of human leukocyte antigen sharing in both types of recurrent aborters. The primary aborters shared human leukocyte A and DQ antigens and three or more of the human leukocyte A, B, DR, and DQ antigens. The secondary aborters did not have an excess of sharing at any one locus but they did share three or more of the human leukocyte A, B, DR, and DQ antigens. There was no excess of antipaternal cytotoxic antibodies in any group of aborters, and the primary aborters had a lower level of mixed lymphocyte reaction blocking factor than normal couples or secondary aborters. Previous studies showed that couples in whom a gestational trophoblastic tumor developed in the woman shared human leukocyte B and DQ antigens and three or more of the human leukocyte A, B, DR, and DQ antigens. These studies provide substantial support for the role of recessive genes linked to the major histocompatibility complex in the pathogenesis of recurrent spontaneous abortions and of gestational trophoblastic tumors. (Am J Obstet Gynecol 1990;163:178-88.)

Key words: Human leukocyte antigen sharing, primary recurrent spontaneous abortion, secondary recurrent spontaneous abortion, genetics of reproduction, genetics of cancer

There is a considerable amount of literature with regard to both human beings and experimental animals on the cause of recurrent spontaneous abortion in the absence of anatomic, chromosomal, or hormonal abnormalities and infections. A variety of studies, but not all of them, indicate that there is a higher prevalence of sharing human leukocyte antigens (HLA) between husband and wife in these couples than there is in normal fertile couples.[1, 2] However, the difficulties with many of these studies are the relatively small number of couples examined and the unspecified or mixed ethnic composition of the populations. These variables could confound the statistical and genetic interpretation of the data. Nonetheless, the analysis of the aggregated data strongly supports the conclusion that there is a greater HLA sharing in couples in whom the woman experiences recurrent pregnancy losses. There are also reports that women who have had recurrent spontaneous abortions with one partner may not have them with another partner.[3] These observations are consistent with our hypothesis about the relationship between recurrent fetal losses and susceptibility to cancer and recessive genes linked to the major histocompatibility complex.[1, 4-7]

To test this hypothesis directly, we undertook a series of studies in a large, ethnically homogeneous Chinese population in Taiwan. The first study[8] showed that there was a significant level of HLA sharing in couples in whom a gestational trophoblastic tumor developed in the woman: the sharing involved HLA-B, HLA-DQ, and three or more of the HLA-A, B, DR, and DQ antigens. The present study examines HLA sharing in the couples from this same population who underwent primary or secondary recurrent spontaneous abortions, and it shows that there is a significantly increased level of HLA sharing in these couples when compared with normal fertile couples in the same population. Thus,

these studies provide further evidence for our hypothesis that major histocompatibility complex–linked recessive genes affect both fetal viability and susceptibility to cancer.

Material and methods

All of the patients used in this study were from the Obstetrics Clinic of the National Taiwan University Hospital. None of the women with recurrent spontaneous abortions had any anatomical, chromosomal, or hormonal abnormalities; infectious diseases; or lupus anticoagulant, antinuclear antibodies, or anticardiolipin antibodies. The husbands all had normal semen analyses. The primary aborters had three or more consecutive spontaneous abortions and no live births. The secondary aborters had one or more live births and then three or more consecutive spontaneous abortions. The normal fertile controls matched for age with the patient population had two or more live births and did not have a history of spontaneous or induced abortions.

The HLA typing was done by the microcytotoxicity test with reagents calibrated against the standard antisera previously described.[9] Because of the high prevalence of HLA-Bw4,Bw6 and HLA-DRw52,DRw53 in the population, these antigens were not used in determining antigen sharing. The typing for HLA-C was done both in the patients with recurrent spontaneous abortions and in the patients with gestational trophoblastic tumors reported previously[8] because of the recent report[10] that there are HLA-C–like antigens in several cultured choriocarcinoma cell lines and the possibility exists that such a "nonclassical" class I major histocompatibility complex antigen could be involved the genetic basis of fetal losses and cancer. The significance of the HLA antigen sharing was determined by the χ^2 test with the use of a 2 by 2 contingency table, and $p < 0.05$ was taken as the level of significance.

All the sera used for antibody and mixed lymphocyte reaction blocking activity were taken for analysis after the last pregnancy recorded in the various groups of patients. The maternal antipaternal lymphocytotoxic antibodies were determined by the microlymphocytotoxicity assay with the use of rabbit complement.[11] The husband's lymphocytes were separated into T and B cells on a nylon wool column and then resuspended in Roswell Park Memorial Institute 1640 medium (3×10^6 cells/ml). Each cell type was tested separately, and the results were the same. Deactivated maternal serum was added in doubling dilutions to 1 μl of the husband's cells in the microtiter plates, and the assays were performed in triplicate. The reaction mixture was incubated at 37° C or 4° C for 1 hour, complement was added and the mixture was incubated for another hour. Eosin and formalin were added, and the plates were examined microscopically. Cytotoxicity ≥30% was considered to be a positive reaction.

The mixed lymphocyte reaction–blocking activity[12, 13] was measured with lymphocytes prepared from heparinized peripheral blood by Ficoll-Hypaque gradient centrifugation. The husband's lymphocytes (stimulator cells) were treated with 50 μg/ml mitomycin C for 30 minutes at 37° C and then washed three times with Roswell Park Memorial Institute 1640 medium. Cultures were set up in triplicate in flat-bottom microtiter plates (Nunc 63320 U96, Rockilde, Denmark) with 1×10^5 maternal (responder) and 1×10^5 paternal (stimulator) lymphocytes in 200 μl of Roswell Park Memorial Institute 1640 medium containing either 20% inactivated pooled male AB sera (control) or 20% inactivated maternal (test) serum. The cultures were incubated in a humidified incubator containing 5% carbon dioxide at 37° C for 6 days. After 18 hours' incubation with tritiated thymidine (0.5 μCi/well), the cells were harvested on a glass fiber filter, the filters were counted in a liquid scintillation counter, and the results were expressed as the mean counts per minute. The percentage blocking by the maternal serum was calculated as:

$$\left(1 - \frac{\text{Mean cpm test cells}}{\text{Mean cpm control cells}}\right) \times 100$$

where *cpm* is counts per minute. Blocking of the mixed lymphocyte reaction ≥20% was considered to be indicative of the presence of blocking factor in the serum.

Results

The HLA typing was performed on 91 couples with primary recurrent spontaneous abortions (Table I) and on 32 couples with secondary recurrent spontaneous abortions (Table II). Twenty-nine normal fertile couples were also typed (Table III), and their data were added to those of the 22 normal couples previously reported[8] to give a total normal population of 51 couples. These three groups of patients (Table IV), the previously reported 22 normal fertile couples,[8] and the 26 couples in whom the woman had a gestational trophoblastic tumor[8] were also typed for their HLA-C antigens (Table IV).

Maternal antipaternal cytotoxic antibodies and mixed lymphocyte reaction blocking factor were determined in 70 of 91 primary aborting couples and in 29 of the 32 secondary aborting couples (Table V). There was no correlation between HLA sharing and the production of cytotoxic antibodies or between HLA sharing and the presence of mixed lymphocyte reaction blocking factor in either of the aborting groups or in normal fertile couples.

The HLA sharing in both primary and secondary spontaneous aborters was greater than that in normal fertile couples, but the pattern of sharing was different (Table VI). The primary aborters shared HLA-A, HLA-DQ, and three or more of the HLA-A, B, DR,

*Exclusive of Bw4,Bw6 and DRw52,DRw53.

†Blank; therefore, it is different from the other DQ antigen typed.

and DQ antigens; whereas the secondary aborters did not have an excess of sharing at any one locus but did share to a significantly greater extent two or more of the HLA-A, B, and DR antigens and three or more of the HLA-A, B, DR, and DQ antigens. The sharing pattern in the couples in whom a gestational trophoblastic tumor developed in the woman more closely resembled that in the primary aborters: they shared HLA-B, HLA-DQ, and three or more of the HLA-A, B, DR, and DQ antigens. There was no significant difference in cytotoxic antibody formation between those couples with normal fertility and those with primary or secondary spontaneous abortions (Table VI). Fewer primary aborters had a significant level of mixed lymphocyte reaction blocking factor in their sera than did the secondary aborters, and the latter did not differ significantly from normal fertile couples (Table VI).

Comment

The same large, ethnically homogeneous Chinese population in Taiwan was examined for HLA sharing in couples with primary or secondary recurrent spontaneous abortions, in couples in whom the woman had a gestational trophoblastic tumor,[8, 14] and in normal fertile couples. There was significant HLA sharing in excess of that seen in normal fertile couples in all three disease groups, and the feature common to all was sharing three or more of the HLA-A, B, DR, and DQ antigens.

The observation that sharing three or more HLA antigens was the primary pattern suggests that sharing the segment of the chromosome that carries the major histocompatibility complex is critical and not the sharing of antigens at a specific HLA locus. This conclusion is consistent with the one drawn from pooled HLA sharing data,[1, 2] and it supports our hypothesis that major histocompatibility complex—linked recessive genes are involved in recurrent fetal losses and in susceptibility to cancer.[4, 5, 8] This hypothesis is all the more cogent now because all the data in our studies were generated from the same large, ethnically homogeneous population. The difference in the pattern of HLA antigen sharing between primary and secondary recurrent spontaneous aborters suggests that there may be a somewhat different genetic basis for the two types of pregnancy loss.

The antibody responses observed in this study may be interpreted in the light of our recent experimental embryo transfer studies in allogeneic matings involving the WF (*u* haplotype) and DA (*a* haplotype) strains of rats.[15] There are two types of major histocompatibility complex histocompatibility antigens in the DA strain: the major allele-specific class I transplantation antigen A^a and the pregnancy-associated class I antigen Pa that carries only broadly shared antigenic determinants. Both antigens are synthesized in the trophoblast cells, but only the Pa antigen is expressed on the surface of the trophoblast cells in the WF (female) and DA (male) mating and the antibody response to it does not affect the heterozygous fetuses. However, when a DA and DA homozygous embryo is transferred to a pseudopregnant WF female, there is an antibody response to the A^a transplantation antigen as well as to the Pa antigen, but the anti-A^a antibody is not deleterious: the pregnancy develops normally and produces normal offspring. However, in some transfers the DA homozygous embryos die and are resorbed. In this situation, only anti-Pa antibodies are formed, as in the natural mating. These findings suggest that the anti-Pa antibodies are elicited first and that the anti-A^a antibodies appear later, depending on the amount of antigen to which the maternal immune system is exposed.

In the human pregnancy, the mixed lymphocyte reaction blocking factor, which is presumably an antibody, may be analogous to the anti-Pa antibody, and the antipaternal cytotoxic antibodies may be analogous to the anti-A^a antibodies. In the normal situation, the antigenic stimulus of several term pregnancies elicits the highest response because approximately three fourths of normal pregnancies had mixed lymphocyte reaction blocking factor. In the secondary aborters, the one or two pregnancies that were carried to term before the onset of recurrent fetal losses would provide a similar, but less potent, stimulation. This interpretation is consistent with the presence of mixed lymphocyte reaction blocking factor in the sera of approximately one half the secondary aborters. Finally, the primary aborters would be exposed to a minimal antigenic stimulus because they would not have carried any pregnancies to term, and they should have the lowest level of mixed lymphocyte reaction blocking factor. They do; only one fourth of them had it. In this interpretation then, the presence of mixed lymphocyte reaction blocking factor would reflect the type of pregnancy rather than determine it. The antipaternal cytotoxic antibodies are the antibodies to the allele-specific class I antigens and are the tissue-typing reagents in both species.

In summary, HLA sharing occurs in significant excess of normal in couples with primary or secondary recurrent spontaneous abortions and in couples in whom a gestational trophoblastic tumor develops in the woman. This observation supports the hypothesis about the genetic cause of these defects, at least in certain populations; several other well-defined populations should be tested to extend explicitly this generalization.

Whereas the pattern of HLA antigen sharing may differ in each of the disease groups, all of them share three or more of the HLA-A, B, DR, and DQ antigens, and this observation suggests that recessive loci in the major histocompatibility complex region of the chromsome other than the HLA loci themselves play a major role in the cause of recurrent spontaneous abortions and of gestational trophoblastic tumors.

Studies of the spontaneous motility and the effect of histamine on isolated myometrial strips of the nonpregnant human uterus: The influence of various uterine abnormalities

Inocencia Martinez-Mir, MD, PhD, Luis Estañ, MD, PhD, Francisco J. Morales-Olivas, MD, PhD, and Elena Rubio, MD, PhD
Valencia, Spain

We investigated the spontaneous uterine activity of isolated corpus uteri myometrial strips from 30 patients with nonpathologic myometrium, 26 patients with uterine myoma, 23 patients with uterine adenomyosis, and three patients with uterine malignancy. We also investigated the influence of these conditions on the response of the uterus to histamine. The results show the same qualitative cyclic changes of the spontaneous motility of isolated myometrial strips throughout the menstrual cycle in all the abnormalities studied. These changes are characterized by a low amplitude and high frequency of spontaneous contractions in the proliferative phase and lower frequency with higher amplitude of contractions in the secretory phase. The isolated strips from patients with myomas present the highest spontaneous activity in reproductive age and preclimacteric women, but not in menopausal women. Histamine produced concentration-related contractions that are not significantly different in all the myometrial strips studied. (Am J Obstet Gynecol 1990;163:189-95.)

Key words: Isolated human uterus, histamine, uterine motility

It has been reported that the spontaneous motility of isolated muscular strips of the human uterus varies widely, with sexual phase, anatomic origin of the strip, pregnancy, and the experimental conditions used.[1-3] Moreover, several authors have shown that there are wide variations in the frequency and force of contractions, as well as the response to drugs, of human myometrial strips from different uteri, although the cause of these large variations is still obscure.[3-5] Conversely, many studies of the isolated human uterus have been done with no consideration for the clinical diagnosis in each case; therefore the uterine abnormality of the women who had operations could be a source of the variation in the results described.

In this investigation we studied the spontaneous uterine activity of isolated myometrial strips from patients with various uterine pathologic conditions and investigated the influence of those pathologic conditions on the response of the corpus uteri to histamine.

Material and methods

Myometrial tissue was obtained from 82 women undergoing hysterectomy because of various gynecologic pathologic conditions. A sample of each uterus obtained was sent for histologic examination to check the pathologic diagnosis and the phase of menstrual cycle. The specimens were divided on the basis of their final diagnosis as follows: group 1: 30 patients who underwent hysterectomy for gynecologic conditions that did not affect the uterus served as normal control subjects; group 2: 26 patients with uterine myoma; group 3: 23 patients with uterine adenomyosis; and group 4: three patients with uterine malignancy.

Since it has been reported that menopause and the phase of the sexual cycle may influence uterine motility, subjects were then separated into subgroups according to the classification used by Sandberg et al.[1] as follows: proliferative group, 18 patients aged 29 to 51; secretory group, 20 patients aged 37 to 53; preclimateric group, 13 patients aged 41 to 57; and menopausal group, 31 patients aged 52 to 78.

Isolated strips of uterus. Immediately after abdominal hysterectomy, muscle strips from an intermediate layer were cut longitudinally from the anterior part of the corpus of the uteri. The tissue was rapidly immersed in a Jalon solution of the following composition: sodium chloride 155.17 mmol/L, potassium chloride

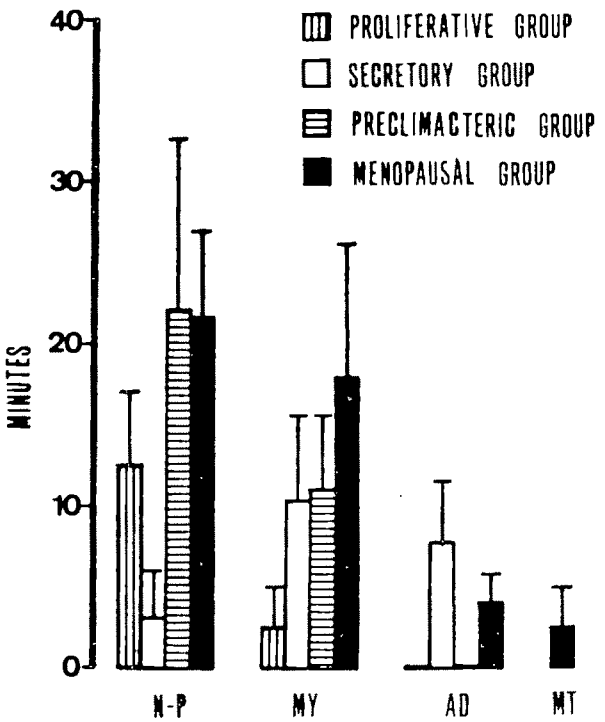

Fig. 1. Time in minutes for myometrial strips to start spontaneous motility. Strips were taken from uteri with nonpathologic conditions *(N-P)* (n = 46), myomas *(MY)* (n = 39), adenomyosis *(AD)* (n = 25), and malignant tumors *(MT)* (n = 5). Each value is the mean ± SEM.

5.68 mmol/L, calcium chloride 0.41 mmol/L, sodium bicarbonate 5.95 mmol/L, glucose 2.78 mmol/L; samples were then transported to the laboratory. The tissue samples were stored at 4° C until the next day. Muscle strips measuring approximately 2 × 3 × 35 mm were dissected and then mounted in a 20 ml organ bath containing Jalon solution at 31° C and were continuously gassed with 95% oxygen and 5% carbon dioxide. Isometric tension was recorded by a Ugo Basile C40 7010 transducer (Milan, Italy) connected to a Ugo Basile mod Gemini 7070 recorder. Initial tension was set at 1 gm and the preparations were undisturbed for 1 hour before any drugs were added. At the end of this period the concentration-response curve to histamine was obtained by cumulatively adding the drug at increments of 1 log unit. Only one complete dose-response curve to histamine was constructed for each myometrial strip because tachyphylaxis to histamine has been reported for the rat uterus.[6, 7]

Immediately after completion of the pharmacomechanical studies, the tissue was removed from the bath, heated for 24 hours, and then weighed on a precision balance.

Analysis of data. The spontaneous activity of the muscle strips developed in these experimental conditions was evaluated as described previously[7] in terms of (1) isometric tension, (2) frequency of contraction, (3) functional activity, and (4) period of time necessary for the tissues to develop spontaneous activity.

The values for the isometric tension developed (expressed in milligrams of force per milligram of tissue dry weight) were obtained by calculating the mean amplitude of all the contractions recorded in a 10-minute interval. The frequency of contractions represents the number of contractions in the same period of time, and functional activity corresponds to the product of these two parameters expressed in arbitrary units. The period of time before the beginning of spontaneous uterine activity is expressed in minutes.

The responses of the tissue resulting from the addition of histamine were directly determined as changes in isometric tension and transformed into tension (i.e., force per gram of tissue dry weight). The 50% effective concentration (EC_{50}) was calculated graphically from a plot of log concentration versus percentage of the maximum response (E_{max}) produced by each agonist in individual experiments.

All data are shown as mean ± SEM. Statistical analysis of the data was done with Student's t test at the 5% significance level.

Histamine was used as dihydrochloride (Sigma Chemical Co., St. Louis) and prepared in Jalon solution before being added to the bath. Drug concentrations refer to the free base and are expressed as a final bath concentration in moles per liter.

Results

The spontaneous motility of muscle strips isolated from 82 uteri was studied; 37.5% of all isolated strips showed spontaneous activity during the first hour in the organ bath. The mean ± SEM in minutes required for the uterine strips to start spontaneous motility is summarized in Fig. 1. There was a wide variability among the groups of women studied.

Spontaneous motility of isolated uterine strips from patients with normal menstrual cycles. Spontaneous motility occurred in 35.9% of the muscle strips from uteri without pathologic conditions, 39.6% of the muscle strips from uteri with myomas, and 37.2% of the muscle strips from uteri with adenomyosis. Fig. 2 shows the frequency, force of contraction, and spontaneous uterine activity values obtained in the control group, as well as the myoma and adenomyosis groups. The spontaneous uterine activity in the myoma group was significantly higher than the value obtained in the control group. This latter value was not significantly different from that obtained in the adenomyosis group.

The highest spontaneous uterine activity observed in the myoma group was a result of a marked increase in force of contraction, which was not accompanied by any significant changes in frequency of contractions.

Table I shows the frequency, force of contraction, and spontaneous uterine activity of the control, myoma, and adenomyosis groups in relation to the hormonal phase. It can be seen that the uterine activity developed by the isolated strip from uteri in the secretory phase was similar to the uterine activity developed in the proliferative phase, for each of the three groups.

In addition, in the control group the statistical analysis revealed that the myometrial strips isolated from uteri in the secretory phase developed a spontaneous motility with a significantly lower force of contraction than that of the spontaneous motility of strips isolated from uteri in the proliferative phase. In contrast, the frequency of contraction of myometrium was higher in secretory phase uterus than in proliferative phase uterus. These results were similarly observed in both of two other groups (uteri with myomas and adenomyosis).

Spontaneous motility of isolated uterine strips from preclimacteric patients. The percentages of isolated strips that developed spontaneous motility were 33.3%, 40%, and 50% in preparations from uteri with no abnormalities, myomas, and adenomyosis, respectively.

Fig. 3 shows that the uterine activity of the isolated strips from a uterus with myomas was greater than that observed in preparations isolated from both uteri with adenomyosis and uteri with no pathologic conditions. These differences were a result of a significant increase in force of contraction, which was not accompanied by any significant changes in frequency of contractions.

No significant differences in uterine activity (i.e., frequency and force of contractions) were found among uteri with nonpathologic conditions, uteri with myomas, and uteri with adenomyosis in women with a normal menstrual cycle and uteri that were nonpathologic, had myomas, or adenomyosis in preclimacteric patients.

Spontaneous motility of isolated uterine strips from menopausal patients. The percentages of isolated strips developing spontaneous motility in uteri with no abnormalities, myomas, adenomyosis, and malignant tumor groups were 30.1%, 20%, 31.8%, and 31.3%, respectively.

Fig. 4 shows that the values of uterine activity of the isolated strips from nonpathologic, myoma, and adenomyosis groups were not significantly different, with no modifications in force and frequency of contractions. In contrast, the value of uterine activity was significantly higher in isolated strips of uteri with malignant tumors compared with each of the three groups in menopausal women. This increase in spontaneous uterine motility was mainly a result of an increase in force of contractions.

Both uterine activity and force of contraction values were markedly reduced in isolated strips of uteri with

myomas compared with those of uteri with myomas of climacteric and women with normal cycles.

In women with nonpathologic uteri, there was a general tendency toward lower uterine activity and force of contractions with decreasing ovarian function. This

tendency was revealed to be significant in the menopausal group.

Effect of histamine. Histamine (10^{-8} to 10^{-3} mol/L) induced concentration-related contractions of the human uterine strips. The force of contraction increased and reached a maximum with 10^{-4} mol/L histamine. The EC_{50} value determined from concentration-response curves was $5.2 \pm 1.0 \times 10^{-5}$ mol/L. The uterine response to histamine varied according to the amount of spontaneous activity shown by the preparation. When the uterine strip exhibited weaker spontaneous activity, this activity declined progressively during a concentration-response curve to histamine. Conversely, when the spontaneous activity developed by the uterine strip was higher, histamine, at the lowest concentrations, produced a superimposed contraction; at higher concentrations, the relaxations between contractions was incomplete, so the force of contractions was increased in a manner similar to that observed when a weaker spontaneous activity is present.

Table II shows that for women with normal menstrual cycles, histamine produced the same maximum degree of contraction and had similar EC_{50} values in each group irrespective of the uterine pathologic condition. In contrast, muscle taken during the secretory phase of the menstrual cycle developed a higher maximal response to histamine than muscle taken during the proliferative phase. However, this difference in responsiveness was not statistically significant (Fig. 5).

The histamine response of myometrial strips from both preclimacteric and menopausal groups was similar to that of the group with normal menstrual cycles. Similarly, the EC_{50} and maximal effect of histamine were unaffected by the pathologic condition of the uterus (Table II).

Comment

The foregoing results confirm previous findings documenting that there was a wide variation in the spon-

taneous contractility of myometrial strips from different uteri.[1-3]

Our results do not support the observation of Lossius and Nesheim[4] who reported that 99% of the muscle strips from nonpregnant uteri showed spontaneous activity. Their study was made with 18 uteri, and the temperature used was 37° C. The greater number and lower temperature used in our study could explain the differences between results. Conversely, our results agree with those of Garrioch,[2] showing that the isolated human myometrium usually begins spontaneous activity within 30 minutes.

It has been reported that uterine spontaneous motility varies according to the phase of the sexual cycle; however, previous reports on differences in spontaneous uterine activity in vitro during the menstrual cycle have been conflicting.[1,2,4,8] Lossius and Nesheim[4] found no modification in the frequency of contraction in relation to hormonal phase. Sandberg et al.[1] found three different types of spontaneous motility in strips from the uterine corpus, although they could not demonstrate any difference between proliferative and secretory phases. However, Garrioch[2] has shown a low amplitude associated with high frequency in the early phase, and that the latter stages are characterized by lower frequency and higher amplitude contractions. Similar observations were found in our study. Moreover, our results are also in agreement with previous in vivo findings.[8]

Our findings in spontaneous activity of the uterus from normal preclimacteric and menopausal women are in accordance with those of Sandberg et al.,[1] who reported a scanty and an intermediate motility in menopausal and preclimacteric groups, respectively. However, the absence of a quantitative study does not permit a more detailed discussion. In addition, similar results have been shown in uterine activity in vivo.[8] Adam et al.[9] have shown marked atrophy in circular and longitudinal uterine layers in preparations taken from ovariectomized guinea pigs. Similar myometrial atrophy during menopause could explain the lower spontaneous uterine activity observed in our study group.

This study explores the possibility that uterine pathologic conditions may mediate changes in spontaneous activity. Our results revealed significant differences between pathologic specimens and normal tissues. In the strips of myomatous uteri, the results show a marked increase in spontaneous uterine activity in both reproductive-aged and preclimacteric women. In contrast, no differences were found when the women were of postmenopausal age. Although in our series no study was done to explain these differences, the occurrence

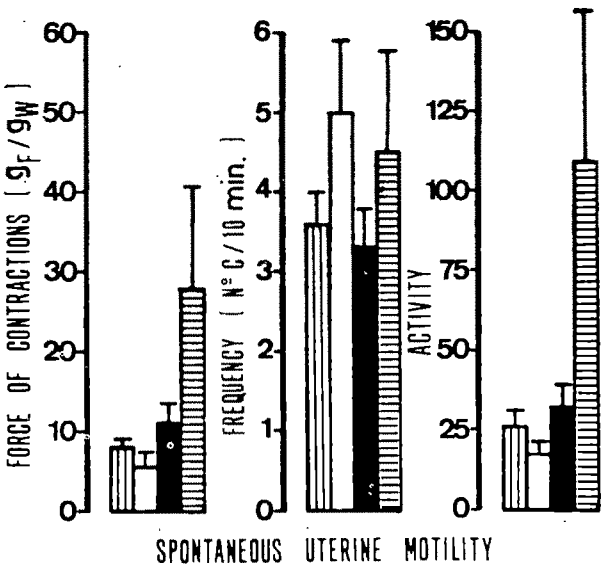

Fig. 4. Frequency (contractions/10 min), force of contraction (g_F/g_W), and spontaneous activity developed by isolated myometrial strips of uteri from menopausal women with nonpathologic conditions (▥) (n = 22), myomas (□) (n = 7), adenomyosis (■) (n = 7), and malignant tumors (▤) (n = 5). Each value is the mean ± SEM.

of increased quantities of steroid receptors in myomas could be related to our results. Soules and McCarty[10] observed normal qualitative cyclic changes in steroid receptors during the menstrual cycle in leiomyomas. Their study agrees with our results, which show two normal cyclic patterns of spontaneous uterine activity in strips taken from uteri with myomas.

Dai et al.[11] suggested that histamine has negligible effects in the human uterus. In contrast, our results show that histamine produces a dose-related contraction of isolated strips of the human uterus and confirm the results described by Farmer and Lehrer.[12] A similar contractile effect of histamine in guinea pig uterus has been reported. Our results also show that the contractile effect of histamine is quantitatively the same, whether the specimen is obtained during either of the two stages of the menstrual cycle or after the menopause. A decrease during aging in sensitivity to histamine has been reported in guinea pig trachea, but as in our results, this change in the contractile effect of histamine is absent in bronchial and parenchymal preparations.[13] In contrast, Eltze[14] failed to find changes in the inhibitory response to histamine on the isolated rat uterus during the menstrual cycle. Similarly, in our study no significant differences in the uterine contractile effect of histamine are shown in the proliferative or secretory phases.

It is well documented that in some airway diseases

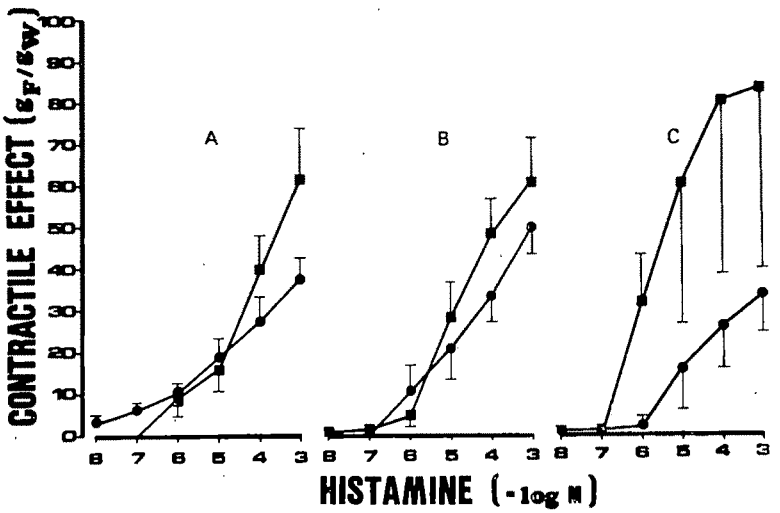

Fig. 5. Dose-response curves to histamine on isolated myometrial strips taken from uteri of women with nonpathologic conditions (**A**), myomas (**B**), and adenomyosis (**C**) of women with active sexual cycles, in proliferative (●) and secretory (■) phases. Each point shows the mean from at least four experiments, and the SEM is shown.

there is hyperreactivity to histamine, and it has been suggested that the existence of hypertrophy and hyperplasia of airway smooth muscle may account for the heightened reactivity to contractile agonists. In this sense, the myometrial strips used in this study were obtained from uteri with pathologic conditions that produce quantitative and qualitative modifications of the smooth muscle mass. Hence, it seems likely that the contractile response to histamine could be modified according to the pathologic conditions. Our results failed to demonstrate a significant modification of EC_{50} and E_{max} of histamine when the dose-response curves of histamine were performed on isolated myometrial strips obtained from different pathologic groups of uteri. The fact that the strips used in our study were taken from macroscopically normal areas of the uterus could explain the lack of modifications in the dose-response curves of histamine found. Pathogenic mechanisms other than those proposed in airway abnormality must occur in uterine pathology and also could explain the different results obtained with histamine in these two tissues.

In summary, the results of this study provide evidence that the spontaneous motility of the isolated strips of human corpus uteri varies according to the uterine pathologic condition and also varies in relationship with menopause. They also confirm the existence of two different sexual phase–related patterns in spontaneous motility of the isolated myometrial strip of human uteri. In addition, it was not possible to demonstrate a significant change in the uterine response to histamine with the uterine abnormality studied.

We thank the staff of the Obstetric and Gynaecologic Service of the Hospital Clinico Universitario for their cooperation in providing specimens of uterus, P. S. Derrick for correcting the English text, and D. Marti for preparing the illustrations.

A new tocolytic agent: Development of an oxytocin antagonist for inhibiting uterine contractions

Laird Wilson, Jr., PhD,[a] Michael T. Parsons, MD,[a] Luella Ouano, MD,[a] and George Flouret, PhD[b]
Chicago, Illinois

A potent oxytocin antagonist has been developed and tested on both the rat and human uterus. In the rat the oxytocin antagonist: (1) inhibited in vitro and in vivo uterine contractions in the nonpregnant animal in response to exogenous oxytocin, (2) inhibited milk letdown, and (3) disrupted the progress of labor. In addition, the oxytocin antagonist inhibited the in vitro contractile response to exogenous oxytocin of human myometrial tissue obtained by cesarean section at term. The results of these studies suggest that the oxytocin antagonist can be used to study the role of oxytocin in labor and has the potential of inhibiting preterm labor in humans. (AM J OBSTET GYNECOL 1990;163:195-202.)

Key words: Oxytocin antagonist, uterine contractions, tocolytic, preterm labor

The contribution of maternal and fetal oxytocin to the initiation and progress of labor is poorly understood. The studies in the literature are conflicting and enigmatic. There are reports that oxytocin levels in the peripheral plasma in humans increase with gestational age or remain unchanged,[1,2] increase at different stages of labor, or show no alterations.[3,4] Similar ambiguities also exist with studies in other species. There are indications the fetus might be an important contributor of oxytocin to labor,[3,5] but other studies refute these data.[6] Also, there are reports that imply that maternal oxytocin does not play a role in parturition in rats[7,8] or humans.[9]

Additional studies have shown that oxytocin receptor levels increase dramatically in uterine tissue just before and at the time of labor in several species, including rats and humans.[10,11] This is interpreted to mean that enhanced secretion of oxytocin is not required and that constant levels of oxytocin in the face of augmented uterine sensitivity to oxytocin would result in incremental changes in uterine activity that culminate in labor.

Recent reports have focused on the development of an oxytocin antagonist for inhibiting uterine contractions.[12-15] The purpose of the present study was to develop a potent oxytocin antagonist to be used to study the role of oxytocin in pregnancy and labor and for the potential clinical use of inhibiting preterm labor in humans. The results of this study show that a potent oxytocin antagonist has been developed; oxytocin appears to be important in the labor process in rats, and the oxytocin antagonist inhibits the response of human myometrial tissue to exogenous oxytocin in vitro. These data suggest that the oxytocin antagonist has the potential of inhibiting preterm labor in humans.

Material and methods

Animals. Virgin (200 to 220 gm) and timed-pregnant (320 to 400 gm) Sprague-Dawley–derived Holtzman rats (Madison, Wis.) were used in these studies. The rats were housed in rooms with controlled light cycles (14 hours light and 10 hours dark) with lights on at 6 AM and given water and food as desired. The protocols in this report have been approved by the Animal Care Committee at the University of Illinois.

Synthesis of oxytocin antagonists. Three oxytocin analogs were synthesized with the solid phase method as previously reported[16]: (1) [β-mercapto-β, β-cyclopentamethylene propionic acid[1], D-Trp[2], Ile[4], Arg[8]]-vasopressin, which will be referred to as oxytocin antagonist 1; (2) its 2-aminodane, 2-carboxylic acid[2] analog; and (3) a D-Phe[2]-oxytocin antagonist analog. Analog 3 was previously reported.[17]

Oxytocin bioassays. Uterine horns from rats in natural estrus were used for the bioassays according to the methods of Holton[18] as modified by Munsick.[19] The tissue was placed longitudinally in a 10 ml organ bath containing van Dyke–Hastings solution with 0.5 mmol/L ionized magnesium at 37° C and gassed with 95% oxygen and 5% carbon dioxide. Ionized magnesium was included in the media since oxytocin antagonistic activity in vitro has been reported to correlate better with in vivo results when it is present.[20] The resting tension on the tissue was 1 gm, and isometric contractions were recorded with a force-displacement transducer FTO3 (Grass Instruments, Quincy, Mass.) and a model 79 polygraph (Grass Instruments). Contractile response of uterine tissue exposed to oxytocin (Bachem, Inc., Torrance, Calif.) for 3 minutes was determined by integrating the area under the curve with a model 7P10 integrator (Grass Instruments). The inhibitory activity (pA_2) of the oxytocin antagonist was determined by the method of Schild.[21] After a cumulative dose-response curve was initially performed with oxytocin, a concentration of oxytocin equal to 90% of the maximum response was used for the antagonist studies. The uterine tissue was exposed to the oxytocin antagonist for 5 minutes before the oxytocin was added; the latter response was then recorded for 1 minute. Four-point assays at three different doses of oxytocin antagonist were performed. The pA_2 estimates were from the average of four or more assays. The pA_2 is defined as the negative logarithm of the molar concentration of an antagonist that reduces the response to the agonist by one-half.[21] Thus the higher the pA_2 value, the more potent the antagonist.

Antidiuretic hormone bioassays. Anti–antidiuretic hormone activity was determined by the method of Jeffers et al.,[22] as modified by Sawyer.[23] Rats were initially gavaged with a volume of 12% ethanol in 0.05% saline solution equal to 5% of body weight. Subsequently the animals were kept hydrated to 8% above initial body weight with 2% ethanol in 0.05% saline solution. The jugular vein was cannulated (PE-50 tubing; Clay Adams, Parsippany, N.J.) for injection of materials and the bladder was catheterized with PE-90 tubing via an abdominal incision for monitoring urine output. Urine drops were counted with a photoelectric pulse sensor transducer (model PPS, Grass Instruments). Body temperature, determined rectally, was maintained at 37° C throughout the experiment with a heat lamp. The end point for the bioassay was urine flow rate. Antidiuretic hormone (Bachem, Inc.) reduces the flow rate and an antagonist diminishes this response. An antidiuretic hormone concentration equivalent to approximately 90% of the maximum response was used as the standard. Ten minutes after the oxytocin antagonist was injected (20 minutes if agonist activity was present), the antidiuretic hormone standard was administered and the response was recorded over a 10-minute period. Concentrations of oxytocin antagonist that altered the response >50% and <50% of the response to antidiuretic hormone alone were used. Three-point assays were performed. The next oxytocin antagonist dose was not administered until the response to antidiuretic hormone was within 10% of the original value. This often took between 30 and 60 minutes. The pA_2 values calculated with this method are substantially lower than if a set time of 30 minutes is allowed between the last antidiuretic hormone injection to the next oxytocin antagonist administration as described by Sawyer et al.[20] The pA_2 is then calculated by the method of Schild.[21] This bioassay was repeated on at least four different animals to obtain a mean pA_2 value for a given antagonist.

In vivo oxytocic assays. Response of the estrous rat uterus in vivo to oxytocin and oxytocin antagonist was tested as described by Bisset et al.[24] and Sawyer et al.[20] with modification. Rats were anesthetized with chloral hydrate (500 mg/kg) intraperitoneally, and a balloon-tipped, water-filled polyethylene catheter (PE-50) was introduced through a small incision at the ovarian end of the uterus and tied in place. Intrauterine pressure was recorded with a Gould P23 ID pressure transducer and a polygraph (Grass Instruments). A PE-50 polyethylene cannula was placed in the jugular vein for infusing oxytocin, oxytocin antagonist 1, or prostaglandin E_2 or $F_{2\alpha}$. One hundred nanomoles of oxytocin and oxytocin antagonist 1 or 300 nmol of prostaglandins was administered as a bolus injection.

Milk letdown studies. Three to four days after delivery rats were anesthetized with chloral hydrate (500 mg/kg) and a PE-50 polyethylene cannula was placed in the carotid artery for infusing heparin–saline solution or oxytocin analogs. The cannula was led to the dorsal surface and exited the skin between the scapula.

Table I. Antioxytocic and antidiuretic potencies of oxytocin analogs

	pA_2 estimates			
	Antioxytocic activity		*Antidiuretic hormone activity*	
Analog No.	*n*		*n*	
1	22	7.62 ± 0.02	8	7.40 ± 0.07
2	2	0	—	—
3	10	7.35 ± 0.01	8	7.66 ± 0.05

See text for description of compound structures (mean ± SEM).

The mothers were fitted with jacket (Alice King Chatham, Los Angeles) and tether, the latter through which the cannula was led outside the cage. The oxytocin analogs were infused at a rate of140 ng/min with a Harvard infusion pump (Harvard Apparatus, South Natick, Mass.). The newborns were reduced to 7 pups per mother at the beginning of the study. Newborn weight gains and the presence of milk in the stomach were monitored as indications of milk letdown. The presence of milk in the stomach is easily observed since the abdominal wall is transparent during the first 15 days of life.

Inhibition of labor. Rats were operated on during day 19 of pregnancy, cannulas were placed in the jugular vein, and a jacket with a tether was placed on the rat as described above for the milk letdown studies. Peptides or control infusions were begun at 9 AM on day 21 of pregnancy and continued until delivery. Peptides were infused at a rate of 140 ng/min.

In vitro oxytocic assays on human myometrium. A full-thickness piece of uterine tissue was obtained from the upper edge of an incision site of a low transverse section at the time of elective cesarean section from eight women at term pregnancy (38 ± 0.5 weeks). A section of transverse myometrial tissue of approximately 1 × 0.2 × 0.2 cm weighing approximately 50 mg was removed and placed in an organ bath, and uterine contractions were monitored as described above for the rat in vitro oxytocic bioassays. Because of the variation in the time of day the samples were obtained and the variation in baseline activity, dose-response curves and pA_2 estimations were not performed in these initial studies. The observation recorded was whether a given amount of oxytocin antagonist 1 could inhibit the response to a given amount of oxytocin and the degree of this inhibition. Responses were determined by integrating the area under the contractile curve for 15 minutes, subtracting the baseline value, and then dividing the results by the tissue weight to give integrated units per milligram of tissue. Informed consent was obtained from all subjects. The study protocol was approved by the University of Illinois Institution Review Board.

Statistical methods. Data in Table II were analyzed by analysis of variance, and, when significant, differences were detected by Duncan's multiple range test.[25] Data in Fig. 5 were analyzed by paired *t* test.[25]

Results

Oxytocin and antidiuretic hormone bioassays. Table I shows the results of the oxytocin bioassay. Of the compounds tested oxytocin antagonist 1 had the highest pA_2 value (7.62). This oxytocin antagonist showed no agonist activity at the highest level tested (10 μmol/L). Note that analog 2 had no antioxytocin activity and thus was only tested in two bioassays. Two assays is a small number, but one must remember that these are four-point assays tested at three different doses; thus each assay was screened for activity 12 times. Oxytocin antagonist activity was not detected in any of these tests.

In the antidiuretic hormone bioassay the estimated pA_2 for oxytocin antagonist 1 was 7.40. No antidiuretic hormone–like agonist activity was detected at the maximum doses tested. Since oxytocin antagonist 1 showed the highest pA_2 in the antioxytocin assay and the lowest pA_2 in the anti–antidiuretic hormone assay on comparison with analogs 2 and 3, it was chosen for further study.

In vivo oxytocic assays. Fig. 1 shows a representative response of in vivo uterine contractions of an estrous rat in response to oxytocin (100 nmol) in the presence and absence of oxytocin antagonist 1. A bolus injection of oxytocin antagonist (100 nmol) blocked the stimulatory activity of oxytocin but not that of prostaglandin F_{2a} or prostaglandin E_2 (300 nmol each). The latter results suggests that oxytocin antagonist 1 has a specific effect on the uterus and not a general, nonspecific tocolytic effect. Also note that about 1 hour after the last injection of oxytocin antagonist 1 the uterus still did not respond to oxytocin but did respond to prostaglandin E_2.

Milk letdown studies. Figs. 2 to 4 illustrates representative results of the milk letdown experiments. Fig. 2 depicts a control animal that received a heparin–saline solution infusion only. The newborn growth rate was constant, and milk was always found in the newborns' stomachs on every observed day. Fig. 3 shows

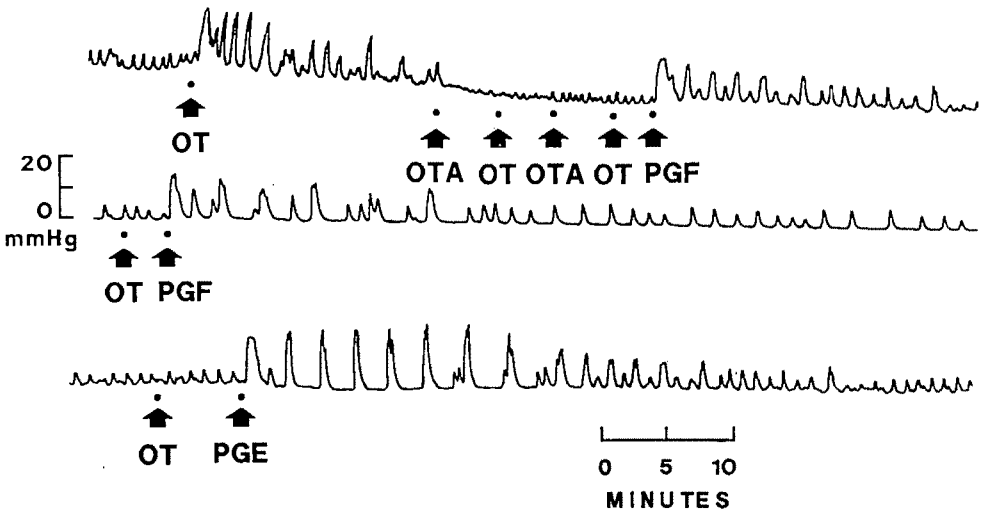

Fig. 1. The in vivo contractile response of an estrous rat uterus to a 100 nmol intravenous bolus injection of oxytocin *(OT)* and the ability of a 100 nmol intravenous bolus injection of the oxytocin antagonist *(OTA)* to block the response to *oxytocin* but not to prostaglandin F or E (300 nmol intravenous bolus, respectively).

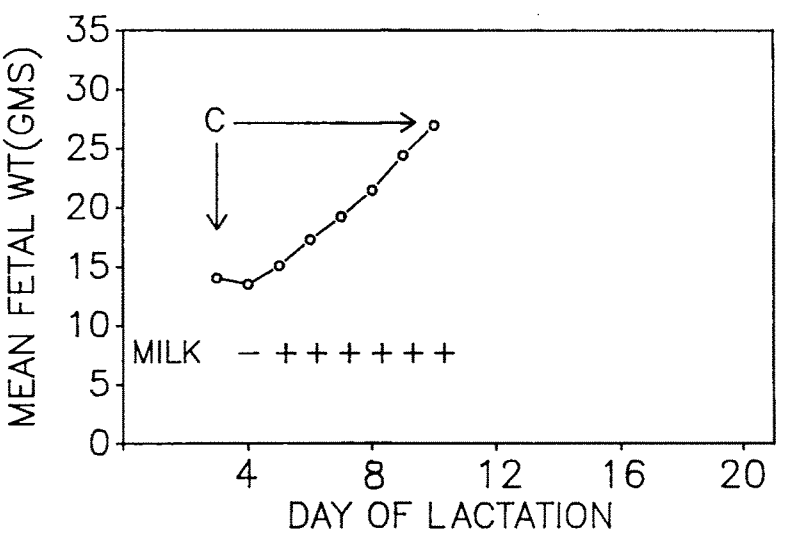

Fig. 2. Relationship of mean weight and the presence (+) or absence (−) of milk in the stomachs of newborn rats to the day of lactation in a mother cannulated on day 3 of lactation and infused with heparin–saline solution *(C)* until day 10.

the effects of oxytocin antagonist 1 on milk letdown. Within 24 hours after oxytocin antagonist 1 was given, the neonatal growth rate was diminished and milk was absent from the newborns' stomachs. Twenty-four hours after oxytocin antagonist 1 infusion was stopped, milk was present in the stomach and growth was renewed. Fig. 4 illustrates the results of infusing analog 2, an oxytocin analog that was found to have no inhibitory activity in the oxytocic bioassay. Neither growth of the newborn nor presence of milk in the stomach was inhibited. These results suggest that the effect observed with oxytocin antagonist 1 on milk letdown was not simply a nonspecific effect, such as a sympathetic discharge that might prevent milk letdown.

It was found in studies not shown that milk letdown began within 6 hours after the infusion of oxytocin antagonist 1 was stopped. This was tested by placing fasted newborns into the cages of mothers every hour after oxytocin antagonist 1 infusion was stopped and observing once every hour the newborns' stomachs for the presence of milk.

Labor inhibition studies. As shown in Table II oxytocin antagonist 1 delayed ($p < 0.05$) the initiation of labor on comparison with the controls that were op-

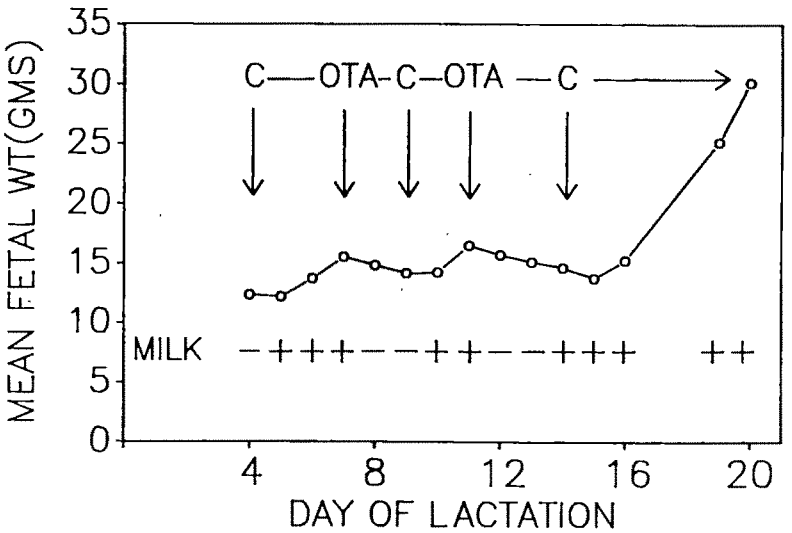

Fig. 3. Similar to Fig. 2, except the oxytocin antagonist was infused at 140 nmol/min on the days indicated. Note the exquisite control of milk letdown via use of the oxytocin antagonist.

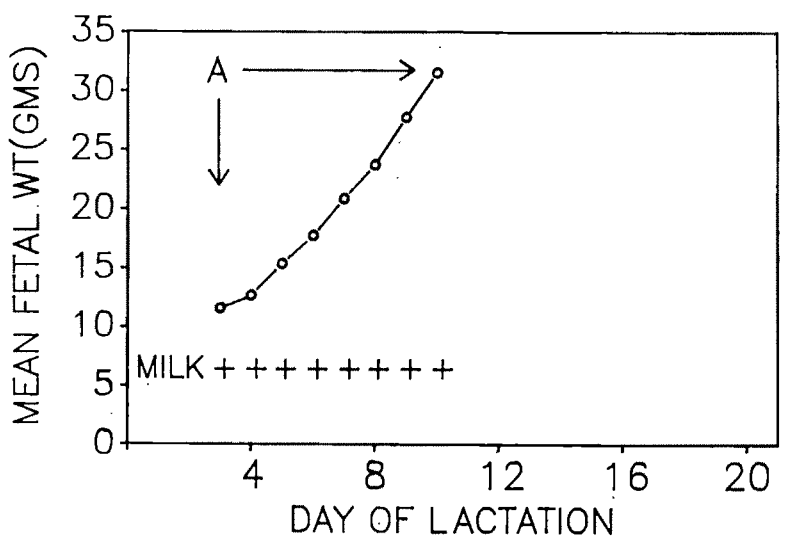

Fig. 4. Similar to Fig. 3, except an inactive oxytocin analog, analog 2 *(A)*, was infused at 140 nmol/min. No inhibition of milk letdown was detected, suggesting the results in Fig. 3 were not due to a nonspecific effect such as a sympathetic discharge.

erated on (40.0 vs 25.9 hours, respectively). However, the most obvious effect was on the length of delivery from the first to the last fetus, which was prolonged ($p < 0.05$) from 8.3 to 16.5 minutes per fetus. The oxytocin antagonist 1–treated group had many fetal deaths that were probably related to hypocontractility. Toxicology studies will have to be performed so that we can accurately assess the potential effects of the oxytocin antagonist on the fetus.

In vitro oxytocic assays on human myometrium. The addition of oxytocin antagonist 1 to the tissue bath containing human myometrial tissue 5 minutes preceding oxytocin administration significantly ($p < 0.05$) diminished the response to oxytocin (Fig. 5). Thus oxytocin antagonist 1 was capable of blocking the response to oxytocin in human tissue, similar to the response by rat uterine tissue in vitro. This suggests that oxytocin antagonist 1 has the potential of inhibiting spontaneous in vivo uterine contractions in humans and possibly preterm labor contractions, if such activity is controlled by oxytocin.

Comment

The development of a potent and specific oxytocin antagonist will be useful for studying the contribution of endogenous oxytocin to uterine contractile activity

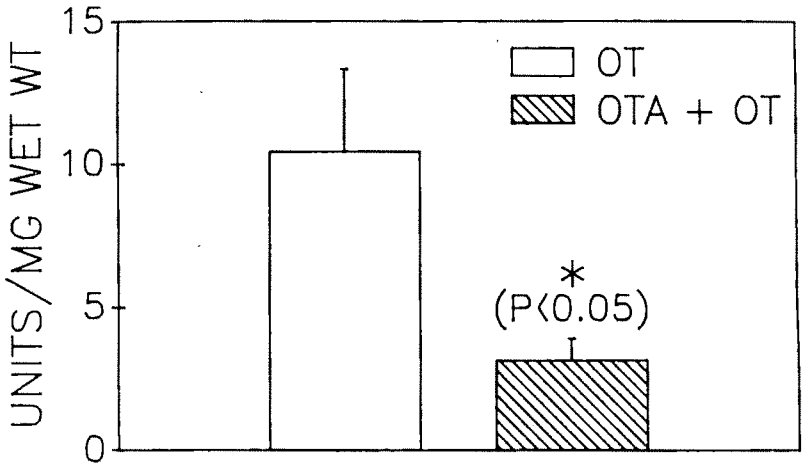

Fig. 5. The in vitro integrated contractile response of human myometrial tissue obtained at cesarean section to 55 nmol/L oxytocin and its inhibition by 35 nmol/L of oxytocin antagonist. The mean inhibition was 67% (N = 8, ±SEM).

Table II. Effect of the oxytocin antagonist on delivery time and progress of labor in the rat

	n	*Initiation of delivery (hours) beginning on day 21*	*No. of fetuses*	*Delivery time per fetus (min)*	*Fetuses*	
					Alive	*Dead*
Controls	11	18.6 ± 3.1[a]	12.8 ± 0.8[a]	6.4 ± 0.4[a]	13.0 ± 0.7[a]	0.1 ± 0.1[a]

Data with different superscripts are significantly different ($p < 0.05$) from each other (mean ± SEM).

throughout pregnancy and at the time of labor. In addition, it has potentially significant clinical application as a tocolytic for preterm labor. This study reports the development of a potent oxytocin antagonist that has been shown to inhibit in vitro uterine contractions of the estrous rat uterus in response to exogenous oxytocin with an estimated pA_2 of 7.62. The pA_2 estimation would be greater if ionized magnesium had been absent from the bioassay buffer. However, ionized magnesium was added since it has been reported to give better correlations with in vivo activity.[20] In addition, the pA_2 would be enhanced if amplitude of the first contraction rather than integrated area under the curve was used as the end point of the bioassay (e.g., amplitude vs integration: oxytocin antagonist pA_2, 8.4 vs 7.62, respectively). The pA_2 estimate from the antidiuretic hormone bioassay was 7.40; thus the oxytocin antagonist has the potential of inducing diuresis in vivo. There were indications of anti–antidiuretic hormone activity (i.e., increased water uptake) in some, but not all, pregnant rats receiving the oxytocin antagonist.

In addition to inhibiting in vitro uterine contractions, this study also demonstrates that oxytocin antagonist 1 can inhibit in vivo uterine contractions in the rat induced by exogenous oxytocin. It was intriguing to find that the inhibitory effect of an intravenous bolus injection of 100 nmol of oxytocin antagonist 1 lasted for more than 1 hour compared with oxytocin whose effect lasted approximately 15 minutes when given at equivalent doses. This suggests oxytocin antagonist 1 may have a fairly long half-life in vivo, as compared with oxytocin. Since the response to oxytocin antagonist 1 in vitro can be washed away within 15 minutes, this indicates that the effectiveness of the oxytocin antagonist in vivo may not be only via its competition for the oxytocin receptor but via an increased half-life as well. Thus the estimated effectiveness of oxytocin antagonist 1 may actually be greater than anticipated from the pA_2 estimation of 7.62 determined from in vitro oxytocic bioassays, which mainly reflect the interaction of oxytocin antagonist 1 with the oxytocin receptor.

The one unequivocal function for oxytocin is its role in milk letdown. The present study has shown that this process in lactating mothers can be exquisitely controlled by oxytocin antagonist 1. Furthermore, it was shown that the effect of oxytocin antagonist 1 was most likely not via a nonspecific response, such as a sym-

pathetic discharge that would inhibit milk letdown, since an inactive oxytocin analogue (analog 2) had no effect on milk letdown. Besides inhibition of milk letdown, oxytocin antagonist 1 may be interfering with prolactin release and thus lactogenesis. Oxytocin has been implicated in prolactin release.[26] However, since it only took 6 hours after oxytocin antagonist 1 infusion was stopped for milk to be detected in the newborn's stomach, this effect, if any, is not profound or long-term. This is an important observation since women taking an oxytocin antagonist to prevent preterm labor may want to nurse their child soon after delivery. This study in rats, as well as in pregnant baboons (unpublished observations), indicates this should not be a problem.

When given to pregnant rats about to deliver, oxytocin antagonist 1 appeared to delay labor, but more apparent was that it prolonged the progress of labor. This suggests that endogenous oxytocin may be more important in the progress and not the initiation of labor in the rat. Because of the limited supply of oxytocin antagonist 1 a dose-response study was not performed in vivo in these initial studies. Perhaps at higher doses the actual initiation of labor can be delayed. Further studies will be needed to determine this possibility.

The observation that about half the newborns were dead at delivery was not surprising considering the prolonged labor that occurred. It is unlikely that oxytocin antagonist 1 is contributing directly to the fetal deaths. However, this will only be resolved by toxicology studies directed toward this specific question.

Finally, in initial attempts to determine if oxytocin antagonist 1 will be effective in humans, in vitro studies on eight separate myometrial tissues showed that oxytocin antagonist 1 could inhibit the myometrial contractile response to exogenous oxytocin. This, along with recently reported studies by Akerlund et al.,[12] that preterm labor contractions in humans could be inhibited with an oxytocin antagonist, suggests that oxytocin antagonist 1 has the potential of inhibiting preterm labor in women.

The importance of an oxytocin antagonist as a tocolytic is its greater specificity (thus with fewer side effects) in comparison with current modalities of treating preterm labor such as sympathometics, magnesium sulfate, and calcium blockers. However, recent reports of finding oxytocin in tissue other than the hypothalamus and pituitary require reassessment of the potential side effects of the oxytocin antagonist.

In summary, this study has reported the development of a potent oxytocin antagonist (1) that inhibited in vitro and in vivo uterine contractions of the nonpregnant rat uterus in response to exogenous oxytocin; (2) that inhibited milk letdown in the lactating rat, (3) that disrupted the progress of labor in the rat, and (4) that inhibited the in vitro myometrial response to exogenous oxytocin in tissue obtained from women via cesarean section at term.

In conclusion, a potent oxytocin antagonist has been developed that can be used to study the role of oxytocin in uterine contractile activity throughout pregnancy and has the potential for inhibiting preterm labor contractions in humans.

We thank T. Walters and M. Davis for performing the oxytocin and antidiuretic hormone bioassays and I. Lopez for assistance in the manuscript preparation. In addition, we are indebted to Dr. Wilber H. Sawyer, Columbia University, College of Physicians and Surgeons, New York, N.Y., for allowing us to visit his laboratory to learn the antidiuretic hormone bioassay.

Differential sensitivities of fetal muscle groups to *d*-tubocurarine

Hazel H. Szeto, MD, PhD, and Donald J. Hinman, PhD
New York, New York

Nine fetal lambs were instrumented for long-term intrauterine recording of electrocorticogram electrooculogram, electyromyogram of the dorsal neck muscle, the quadriceps femoris, and the diaphragm, monitoring of blood pressure, and measurement of heart rate. *d*-Tubocurarine (0.1 to 0.8 mg) was administered intravenously to the fetus over a 1-minute interval. Increasing doses of *d*-tubocurarine selectively blocked various muscle groups, with the extraocular muscles being the most sensitive. Comparison of the median effective dose for neuromuscular blockade of the extraocular muscles/nuchal muscle/diaphragm was 1:2.5:6. The duration of action of *d*-tubocurarine was directly related to the relative sensitivities of the different muscle groups, which are ranked from most sensitive to least sensitive as extraocular muscles, nuchal muscle, and diaphragm. Fetal electrocorticogram continued to cycle despite total neuromuscular blockade. However, there was an increase in synchronized and mixed activity, which was predominantly due to an increase in cycle numbers, and a decrease in desynchronized activity, which was predominantly due to shorter cycle lengths. During total neuromuscular blockade, there was also a significant decrease in heart rate during synchronized and mixed electrocorticogram states but not during a desynchronized electrocorticogram state, thus resulting in a loss of the heart rate difference normally seen between synchronized and desynchronized states. Fetal blood pressure did not change with total neuromuscular blockade. (AM J OBSTET GYNECOL 1990;163:202-9.)

Key words: *d*-Tubocurarine, pancuronium, neuromuscular blockade, fetal paralysis

Neuromuscular blockers are increasingly being used to prevent fetal movements during a variety of intrauterine fetal therapy such as ultrasonography-guided intraperitoneal or intravascular transfusions or shunt placement.[1-4] Fetal movement makes these procedures more difficult and may increase the risk of injury to the fetus. Direct intramuscular or intravenous administration of either *d*-tubocurarine or pancuronium to the fetus was found to be effective in producing complete fetal paralysis as determined by maternal perception[4] or ultrasonographic monitoring.[3] Both *d*-tubocurarine and pancuronium were found to have a rapid onset of action, and the duration of action was

found to be a function of the dose used. Limited experience to date suggests that fetal neuromuscular blockade is an invaluable adjunct to invasive intrauterine procedures, and the short-term use of neuromuscular blockers appears to be without significant adverse effects.

It has been suggested in a previous study that one concern with total neuromuscular blockade in the fetus is the potential need for emergency delivery because of fetal distress during the procedure.[3] Ultrasonographic monitoring revealed that fetal paralysis may last several hours depending on the drug and the dose given.[3] However, these investigators only reported on fetal movements and did not specifically monitor fetal diaphragmatic movements. Differential sensitivities of muscle groups to nondepolarizing neuromuscular blockers have been reported since the late 1940s.[5] The relative sensitivities of the nonrespiratory muscles in general and the respiratory muscles reflect the therapeutic index or safety margin of the drug. Studies in adults demonstrated that the sensitivity of nonrespiratory muscles was at least twice that of the diaphragm, and the diaphragm recovered twice as rapidly as the other muscles.[6,7] The relative sensitivity of various fetal muscles to nondepolarizing neuromuscular blockers is not known.

The objective of the present study was to describe the dose-response and time-action characteristics of *d*-tubocurarine on different muscle groups in the fetal lamb. In addition, we examined the effects of *d*-tubocurarine on fetal cardiovascular function and electrocortical activity. Chestnut et al.[8] recently reported that intravenous administration of *d*-tubocurarine to the fetal lamb significantly decreased fetal heart rate and arterial pressure while pancuronium significantly increased fetal heart rate and arterial pressure. However, the extent of neuromuscular blockade achieved with the single dose of neuromuscular blocker used was not known. We report here on the effects of varying degrees of neuromuscular blockade on fetal cardiovascular function and electrocortical activity.

Methods

Animal preparation. Nine fetal lambs ranging from 124 to 140 days of gestation were used in this study, in accordance with guidelines approved by the institution for the care and use of animals. Operation was conducted 5 to 29 days before the drug study. Details of the surgical procedure have been published previously.[9] Briefly, polyvinyl catheters were placed in the descending aorta for monitoring of fetal blood pressure and heart rate and in the inferior vena cava for administration of *d*-tubocurarine. Stainless steel electrodes were implanted in the dorsal neck muscle, the quadriceps femoris and the diaphragm for electromyogram recording. Eye movements (electrooculogram) were monitored with a pair of stainless steel screws implanted over the superior orbital ridge, and electrocortical activity (electrocorticogram) was monitored with stainless screws over the parietal cortex.

Study protocol. On the day of the study, the sheep was placed in an experimental cart and simultaneous recording of fetal blood pressure, fetal heart rate, and nuchal and quadriceps electromyogram, diaphragmatic electromyogram, electrooculogram, and electrocorticogram were obtained for a 3-hour control period on a Gould analog recorder with appropriate amplifiers and band-pass filters (electromyogram, 100 to 1000 Hz; electrooculogram, 1 to 10 Hz; electrocorticogram, 1 to 30 Hz). *d*-Tubocurarine was administered intravenously to the fetus over a 1-minute period. A total of four doses was studied (0.1 to 0.8 mg), and the order of dose administration was randomized. Each animal received only one dose of *d*-tubocurarine on any given day and at least 2 days was allowed between studies. Simultaneous recording of all fetal parameters continued until recovery from neuromuscular blockade.

Data analysis. The extent of neuromuscular blockade for each muscle was determined after *d*-tubocurarine administration and represented as a percent of control, with each animal serving as its own control. A log dose-response curve was then constructed for each muscle. From the best-fitting curve, the median effective dose was determined for each of the three muscles. The duration of action of *d*-tubocurarine on the three different muscles was compared by means of both quantal and graded time-action plots. The quantal time-action curve was plotted as the percent of animals with 100% blockade of each of the three muscles as a function of time after *d*-tubocurarine administration. The graded time-action curve was plotted as the percent of control electromyogram amplitude for the three different muscles as a function of time after drug administration.

The electrocorticogram was scored as three distinct states: desynchronized (low-voltage fast activity), synchronized (high-voltage slow activity), and mixed (intermediate voltage activity). The incidence of each of the electrocorticogram states was determined after *d*-tubocurarine administration and compared with predrug control values. The number of cycles of each state per hour and the mean duration of each state also were compared with control values.

Mean fetal blood pressure and fetal heart rate were determined for each electrocorticogram state in the control period and after *d*-tubocurarine administration. Statistical differences were ascertained by two-way analysis of variance with subsequent post hoc tests (Systat statistical software, Evanston, Ill.).

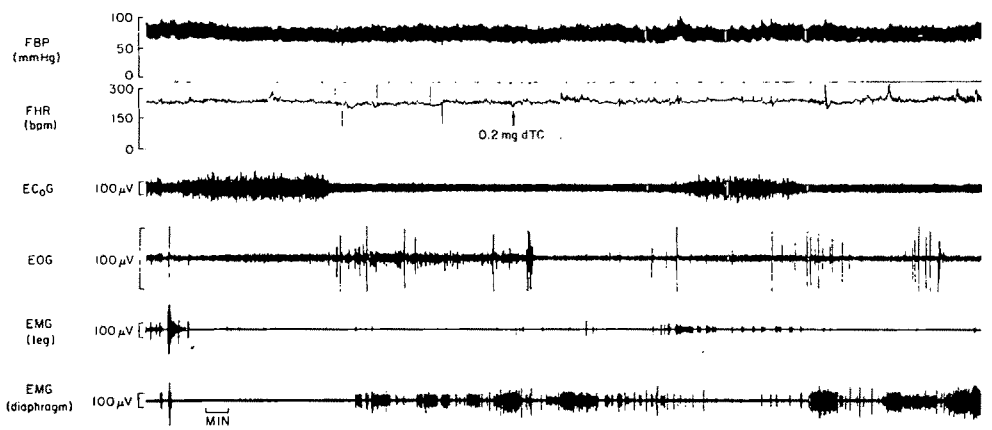

Fig. 2. Polygraphic recording showing effects of 0.2 mg of *d*-tubocurarine administered intravenously over 1 minute to fetal lamb. Note abrupt cessation of all eye movements and a decrease in amplitude of nuchal electromyogram bursts. Diaphragmatic activity was not affected. For explanation of abbreviations see legend to Fig. 1.

Results

Nineteen experiments were performed in nine chronically instrumented animals, with three to six animals studied at each dose level of *d*-tubocurarine.

Fig. 1 shows a representative polygraphic recording obtained during the control period. The electrocorticogram can be seen to alternate between synchronized and desynchronized patterns, with an occasional brief period of a mixed pattern in which there are slower waves of intermediate amplitude. The desynchronized periods are associated with a lower heart rate, rapid eye movements, and breathing movements. On the other hand, the synchronized periods are associated with a higher heart rate, an occasional burst of electromyogram activity in the diaphragm, both tonic and phasic activity in the nuchal and hind limb muscles, and an absence of eye movements.

Administration of 0.2 mg of *d*-tubocurarine to the fetal lamb resulted in an abrupt cessation of all eye movements during a desynchronized electrocorticogram (see Fig. 2). There was also a decrease in the amplitude of the electromyogram bursts in the nuchal muscle during the synchronized electrocorticogram period. Fetal breathing movements were not affected by this dose of *d*-tubocurarine, and cyclic activity in the electrocorticogram was unchanged.

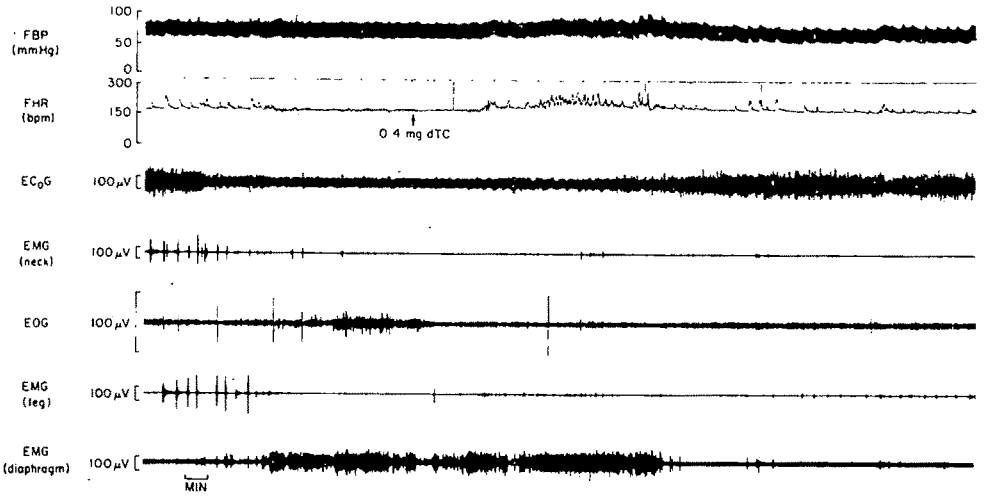

Fig. 3. Polygraphic recording showing effects of 0.4 mg of *d*-tubocurarine administered intravenously over 1 minute to fetal lamb. Note total loss of eye movements during desynchronized electrocorticogram activity and loss of phasic burst activity in nuchal muscle during synchronized electrocortical activity. Hind limb activity was partially suppressed, while diaphragmatic activity remained unaffected. For explanation of abbreviations see legend to Fig. 1.

Table I. Effects of neuromuscular blockade on electrocorticogram activity

	Total time (min)	*Electrocortical pattern*			*No. of cycles*		
		Desynch. (%)	*Mixed (%)*	*Synch. (%)*	*Desynch. (hr^{-1})*	*Mixed (hr^{-1})*	*Synch. (hr^{-1})*

Desynch., Desynchronized electrocorticogram pattern; *Synch.*, synchronized electrocorticogram pattern.

With 0.4 mg of *d*-tubocurarine, there was a total loss of nuchal muscle activity during a synchronized electrocorticogram in addition to the loss of eye movements during a desynchronized electrocorticogram. Hind limb activity was partially suppressed, although there was still no effect on diaphragmatic electromyogram activity (see Fig. 3).

Finally, with the highest dose of 0.8 mg, all muscular activity was blocked as indicated by the total quiescence in all electromyogram recordings, including the diaphragm (see Fig. 4). The electrocorticogram, however, continued to cycle between desynchronized, synchronized, and mixed patterns.

From these recordings it can be concluded that there is a difference in the sensitivity of the various muscle groups to *d*-tubocurarine. Fig. 5 illustrates the dose-response curve for percent neuromuscular blockade of the extraocular, nuchal, and diaphragmatic muscles as a function of *d*-tubocurarine dose. These results show that the extraocular muscles are most sensitive to the neuromuscular blocking effect of *d*-tubocurarine, and the diaphragm is the most resistant. Extrapolating from the dose that resulted in 50% blockade, the relative sensitivity of the three muscle groups is as follows; extraocular muscles, 1; nuchal muscle, 2.6; and diaphragm, 6. Thus the extraocular muscles are six times more sensitive to *d*-tubocurarine than the diaphragm.

Fig. 6 illustrates the time course of recovery from total neuromuscular blockade after the highest dose of *d*-tubocurarine (0.8 mg). The top panel is a plot of the percent of animals with 100% blockade as a function of time after *d*-tubocurarine administration. Immediately after drug administration, all animals had complete blockade of the extraocular muscles and of the nuchal and diaphragmatic muscles. By 6 hours later diaphragmatic activity had been recovered in all animals. On the other hand, the extraocular muscles were still completely blocked in 100% of the animals.

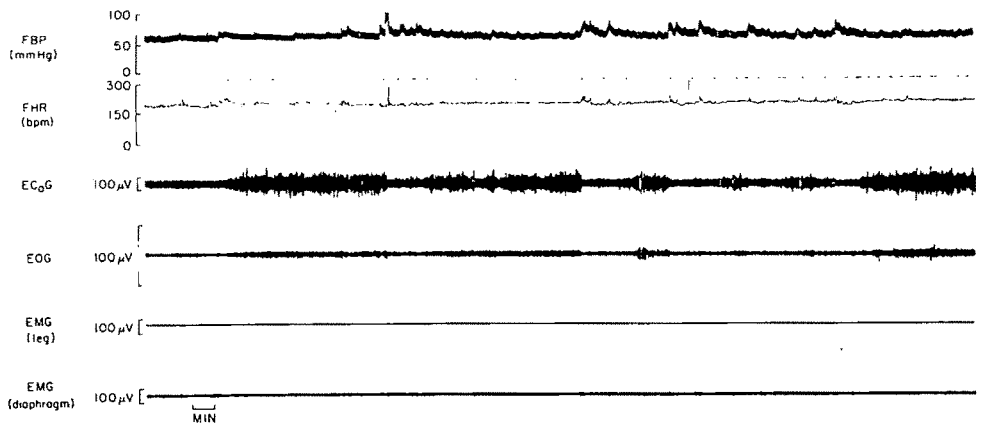

Fig. 4. Polygraphic recording obtained after administration of 0.8 mg of *d*-tubocurarine to fetus. Note total quiescence in all electromyogram recordings. The electrocorticogram, however, continued to show cyclic activity. For explanation of abbreviations see legend to Fig. 1.

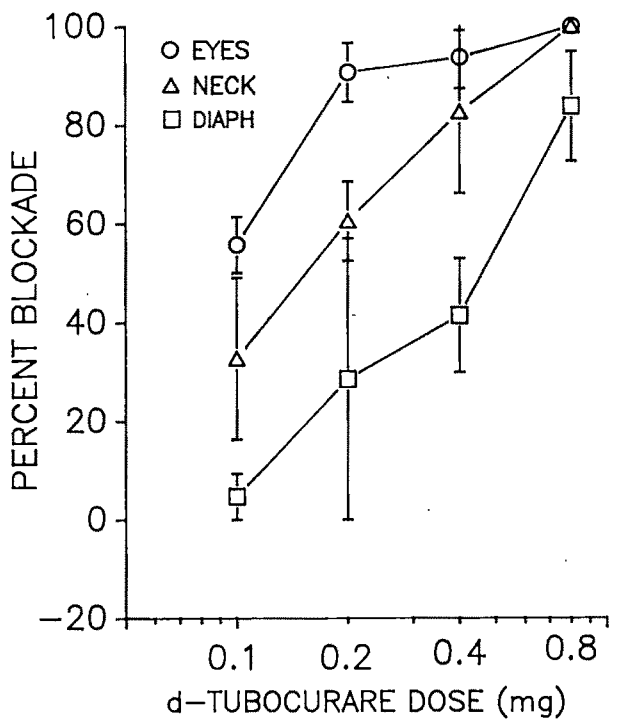

Fig. 5. Dose-response curve showing percent neuromuscular blockade for three muscle groups as function of *d*-tubocurarine dose. ○, Extraocular muscles; △, nuchal muscle; □, diaphragm.

Fig. 7 is a plot of the percent of electromyogram amplitude for the diaphragm and nuchal electromyogram bursts, as well as the percent of control amplitude for eye movements. As a function of time, there is gradual recovery in the electromyogram amplitude of all three muscle groups, with the diaphragm having the fastest recovery. By 8 to 9 hours the diaphragm electromyogram amplitude has completely recovered. On the other hand, neither the nuchal muscles nor the extraocular muscles had completely recovered even by 9 hours after *d*-tubocurarine administration. The order of recovery for the three muscle groups as illustrated by both the quantal (Fig. 6) and graded (Fig. 7) time-action curves is in agreement with the sensitivity of the three muscle groups to the blocking action of *d*-tubocurarine as illustrated by the dose-response curve in Fig. 5.

The effects of neuromuscular blockade on electrocorticogram activity are summarized in Table I. These data were obtained with the two higher doses of *d*-tubocurarine. Data from the two lower doses were not included since they did not result in diaphragmatic paralysis and their effects on the nuchal muscles were very brief. During complete neuromuscular blockade (6 of the 10 animals studied), there was a decrease in desynchronized electrocorticogram activity and an increase in synchronized and mixed activity. Because of the different duration of time at each level of neuromuscular blockade, the number of cycles of each electrocorticogram state was normalized to number per hour. The results showed that the increase in synchronized activity was due to an increase in cycle numbers, while the decrease in desynchronized activity was due to decreased cycle length. With the return of nuchal electromyogram activity, the time distribution pattern in the electrocorticogram was no longer different from that of the control. In two of the animals, nuchal activity had not yet recovered by the end of the experiment.

Table II summarizes the effects of total and partial neuromuscular blockade on fetal blood pressure and fetal heart rate. In the control period fetal heart rate was significantly higher during the mixed and synchronized electrocorticogram cycles ($p < 0.05$); there was no difference in fetal blood pressure during the

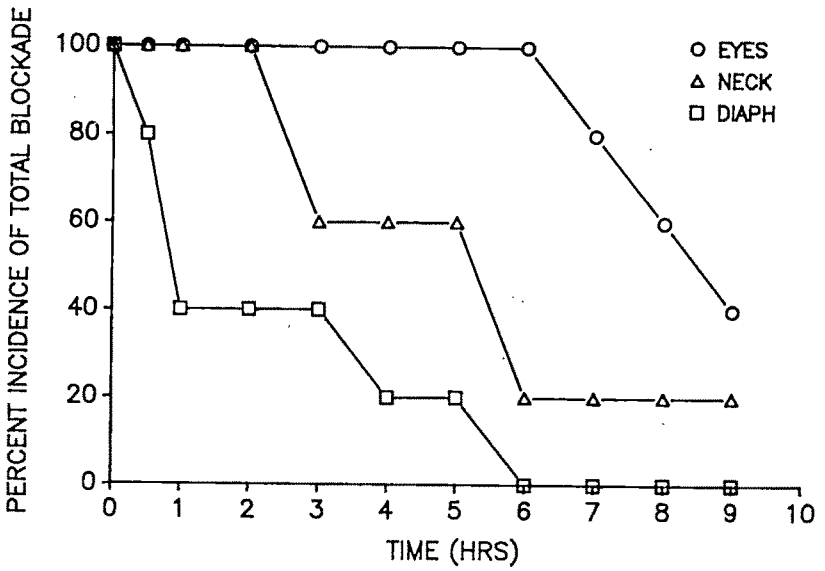

Fig. 6. Time course of recovery from 0.8 mg of *d*-tubocurarine as illustrated by percent of animals with 100% blockade of individual muscle groups as function of time after *d*-tubocurarine administration. ○, Extraocular muscles; △, nuchal muscle; □, diaphragm.

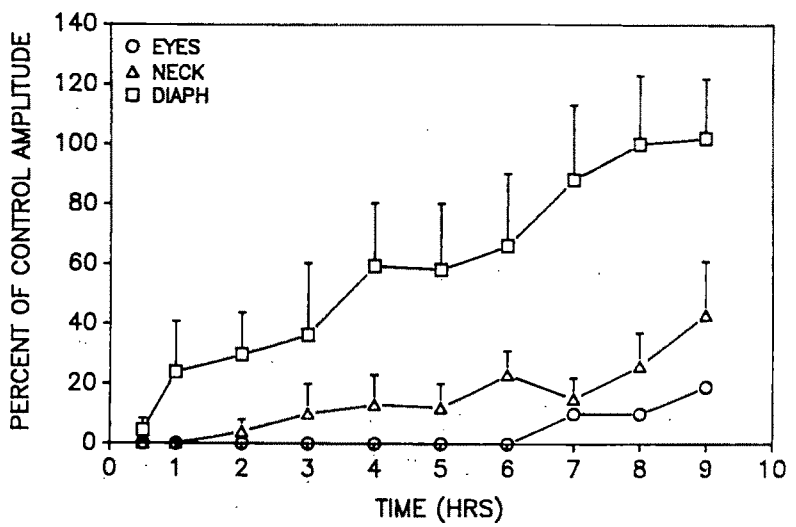

Fig. 7. Time course of recovery from 0.8 mg of *d*-tubocurarine as illustrated by percent of control electromyogram amplitude for three different muscle groups as function of time after *d*-tubocurarine administration. ○, Extraocular muscles; △, nuchal muscle; □, diaphragm.

three electrocorticogram states. During total neuromuscular blockade, there was no change in fetal heart rate during a desynchronized electrocorticogram, but there was a reduction in fetal heart rate in the mixed and synchronized electrocorticogram period, thus resulting in the loss of the heart rate difference between synchronized and desynchronized periods ($p = 0.456$). With the return of nuchal muscle activity, fetal heart rate was higher during a synchronized electrocorticogram than during a desynchronized period, although the difference failed to be statistically significant ($p = 0.091$). Fetal blood pressure did not change with total or partial neuromuscular blockade.

Comment

Previous studies in adult humans and animals demonstrated the relative sensitivity of different muscle groups to the neuromuscular blocking action of *d*-tubocurarine.[6,7] We have found similar differential sensitivities of fetal muscle groups to *d*-tubocurarine. The extraocular muscles were found to be most sensitive, while the diaphragm was the least sensitive. The

*$p < 0.05$, when compared with heart rate during desynchronized electrocorticogram in control animals.

twofold difference in sensitivity between the nuchal and hind limb muscles and the diaphragm suggested that it might be possible to select a dose of *d*-tubocurarine that would provide adequate suppression of total body movements with only limited action on the diaphragm.

The duration of action for the different muscle groups is consistent with each respective dose-response curve. After complete neuromuscular blockade with a dose of 0.8 mg of *d*-tubocurarine, the recovery of the nuchal muscles lagged behind that of the diaphragm by almost 4 to 5 hours. Thus monitoring the recovery of peripheral skeletal muscles does not indicate the state of recovery of the diaphragm.

Similar dose-response and time-action studies have not been carried out in the human fetus. Ch. de Crespigny et al.[1] reported that the fetus remained paralyzed for 9 hours after a 3 mg/kg intramuscular dose of *d*-tubocurarine. Subsequently, Moise et al.[3] reported a duration of fetal paralysis of 3.8 hours after 1.5 mg/kg of *d*-tubocurarine. In neither case did the investigators comment on the recovery of diaphragmatic activity. It is possible, at least with the lower dose of *d*-tubocurarine used by Moise et al.,[3] that blockade of the diaphragm may have been limited.

Complete neuromuscular blockade with *d*-tubocurarine was associated with alterations in the cyclic pattern of the fetal electrocorticogram, resulting in an increase in synchronized and mixed activity patterns and shorter cycle durations. As a quaternary ammonium compound, *d*-tubocurarine is highly ionized at plasma pH and is not expected to cross the blood-brain barrier to any appreciable extent. Previous studies have demonstrated that *d*-tubocurarine administered intravenously to the dog or human is not distributed in any significant amount between the blood and the cerebrospinal fluid.[10] Although the blood-brain barrier in the fetal lamb may not be fully developed at this age, we have previously shown that another quaternary compound, methylatropine, does not appear to have any action on central muscarinic sites after intravenous administration.[11] Thus the mechanism of action of *d*-tubocurarine on the fetal electrocorticogram is not clear. However, rather similar electrocorticogram changes also were reported in adult rats given an intramuscular injection of *d*-tubocurarine (0.5 mg/kg). Power spectral analysis revealed an increase in the proportion of δ- and θ-frequencies in subcortical areas and a reduction of all faster frequencies (6 to 15 Hz).[12] These electrocorticogram changes were believed to be due to the stress of immobilization itself rather than a central action of the drug.

The effects of neuromuscular blocking agents on systemic hemodynamic variables in the adult have been reported by a large number of investigators. Intravenous administration of *d*-tubocurarine is associated with marked hypotension, bradycardia, and a redistribution of regional blood flow.[13-15] The hypotension has been reported to result from a combination of autonomic ganglionic blockade,[16] direct myocardial depression,[14] and histamine release.[17] In contrast, we found no significant effect on fetal blood pressure or fetal heart rate even during complete neuromuscular blockade with *d*-tubocurarine. In a recent study Chestnut et al.[8] reported a significant decrease in fetal arterial pressure and a small decrease in fetal heart rate after a slow intravenous infusion of *d*-tubocurarine to fetal lambs. It should be noted that the dose used in their study (3.0 mg/kg) was approximately tenfold higher than the highest dose given in this study. Even at that dose, the reduction in fetal arterial pressure was <10% compared with the control value. Thus it appears that the administration of *d*-tubocurarine to the fetal lamb is not associated with any detrimental hemodynamic effects.

The reason for the lack of a significant hypotensive response to *d*-tubocurarine in fetal lambs is not known. Guyton and Reeder[16] had suggested that in the adult this may be due to the pooling of blood in the capillaries and veins that results from the sudden paralysis and loss of muscle tone. The fetus has a much higher incidence of rapid-eye-movement sleep, which has been shown to be associated with a lack of muscle tone in the postural muscles.[9] In this study *d*-tubocurarine was usually administered during rapid-eye-movement sleep

to ascertain its blocking action on the extraocular muscles and the diaphragm. The lack of muscle tone during the time of *d*-tubocurarine administration may therefore account for the absence of a significant hypotensive response.

The administration of *d*-tubocurarine did, however, result in loss of the cyclic variation in fetal heart rate that has been shown to be associated with cyclic electrocorticogram activity. Fetal heart rate is normally higher during periods of synchronized electrocorticogram activity,[18, 19] and this has been shown to be due to enhanced sympathetic tone.[19] The loss of cyclic variation in fetal heart rate during complete neuromuscular blockade was due to a decrease in fetal heart rate during synchronized electrocorticogram activity, suggesting that the decrease in heart rate with *d*-tubocurarine may be due to autonomic blockade. Our results also showed that the loss of breathing movements during the desynchronized period did not significantly alter fetal heart rate.

In summary, we have shown that fetal muscle groups also demonstrate relative sensitivities to the neuromuscular blocking action of *d*-tubocurarine. Thus it may be possible to select a dose of *d*-tubocurarine that would provide adequate suppression of fetal movements without prolonged paralysis of the diaphragm. Furthermore, we have shown that *d*-tubocurarine results in minimal adverse effects on fetal cardiovascular function even at doses high enough for complete neuromuscular blockade.

Immunoglobulin G fractions from patients with antiphospholipid antibodies cause fetal death in BALB/c mice: A model for autoimmune fetal loss

D. Ware Branch, MD,[a] Donald J. Dudley, MD,[a] Murray D. Mitchell, DPhil,[a] Kathryn A. Creighton, BS,[a] Thomas M. Abbott, MD,[b] Elizabeth H. Hammond, MD,[b] and Raymond A. Daynes, PhD[b]

Salt Lake City, Utah

We determined whether purified immunoglobulin G from patients with antiphospholipid antibodies causes fetal loss in pregnant mice. Sera were obtained from nonpregnant parous women (group 1) and nonpregnant women with antiphospholipid antibodies and a history of fetal loss (group 2). Pregnant BALB/c mice were given an intraperitoneal injection of 15 mg of IgG on day 8 of pregnancy. Typically, mice treated with IgG from antiphospholipid antibodies aborted within 48 hours. When animals were sacrificed on days 9 to 15, the uterus of each animal was inspected for the presence of live, dead, or resorbing fetuses. In contrast to mice injected with control IgG or saline solution, each mouse injected with IgG from antiphospholipid antibodies aborted and no live fetuses were found ($p < 0.05$). Histologic examination of the uteroplacental interface showed decidual necrosis in the mice treated with IgG containing antiphospholipid antibodies, and immunofluorescent studies also showed prominent intravascular decidual IgG and fibrin deposition. We conclude that IgG from antiphospholipid antibodies of women with fetal loss causes fetal loss in BALB/c mice. It appears that the fetal loss is mediated by IgG binding in the maternal decidual vasculature. (Am J Obstet Gynecol 1990;163:210-6.)

Key words: Antiphospholipid antibodies, fetal loss, antiphospholipid antibody syndrome, recurrent pregnancy loss

The antiphospholipid antibodies lupus anticoagulant and anticardiolipin are risk factors for thrombosis, recurrent pregnancy loss, and fetal death.[1] These serologic and clinical features constitute what is now known as the antiphospholipid antibody syndrome.[2] The cause of pregnancy loss in patients with the syndrome may be uteroplacental insufficiency stemming from a decidual vasculopathy.[1] However, the exact mechanism of fetal loss is unknown, and in spite of the impressive association with antiphospholipid antibodies, there is no unequivocal evidence that fetal loss is caused by immunoglobulins. The purpose of our investigation is to determine whether purified immunoglobulin G from women with antiphospholipid antibody syndrome causes fetal loss in normal, pregnant mice and to study the mechanism of fetal loss associated with antiphospholipid antibodies.

Material and methods

Identification of antiphospholipid antibodies. Lupus anticoagulant was identified in plasma by means of the activated partial thromboplastin time as described previously.[3] Plasma samaples showing clotting times beyond 47 seconds were retested after the patient's plasma had been mixed with an equal volume of normal plasma. A diagnosis of lupus anticoagulant was made when this mixture did not correct to within the normal range (normal laboratory mean + 2 SD).

For testing IgG fractions, 0.4 ml of the fraction was mixed with 0.6 ml of pooled normal plasma. The activated partial thromboplastin time was performed on the resulting mixture. Clotting times <48 seconds were considered normal (normal laboratory mean + 2 SD).

The immunoassay for anticardiolipin antibodies was a modification of the enzyme-linked immunoassay method of Loizou et al.[4] and has been described.[3] Each microtiter plate had a standard curve of known positive samples corresponding to those obtained from the Rayne Institute, St. Thomas Hospital, London. Results were expressed in international units of anticardiolipin antibody, and values ≥20 units for IgG or IgM were considered significant.[2]

Patients and control subjects. Women with antiphospholipid antibody syndrome were identified according to the criteria of Harris.[2] Patient 1, a 31-year-

old woman, had two previous pregnancies that ended in fetal death at 22 and 24 weeks' gestation. She had a popliteal vein thrombosis at age 18 after being prescribed oral contraceptives. Patient 2, a 28-year-old woman, had two previous pregnancies; the first ended in fetal death at 26 weeks' gestation and the second was delivered at 25 weeks' gestation because of severe preeclampsia and fetal distress. The infant of the second pregnancy died within 24 hours of delivery. Patient 3, a 36-year-old woman, had three previous pregnancies that ended in fetal death at 19 to 20 weeks' gestation. She had two episodes of pulmonary embolism, each associated with pregnancy. Patient 4, a 25-year-old woman, had two previous pregnancies ending in fetal death at 32 and 24 weeks' gestation, respectively. Patient 5, a 30-year-old woman, had nine successive pregnancy losses, three of which were second-trimester fetal deaths. She also had two thrombotic episodes, one of which was associated with pulmonary embolism.

All patients had lupus anticoagulant and moderately to strongly positive anticardiolipin IgG (i.e., ≥20 IU at 1:50 serum dilution). Repeated determinations for each antiphospholipid antibody had been performed on each patient. No patient had antinuclear antibodies at a titer >1:80 by the indirect fluorescent antibody method with Hep-2 human epithelial cells. Only patient 4 carried a diagnosis of systemic lupus erythematosus, and the disease was in remission at the time her serum sample was obtained. The other women did not have a clinical autoimmune disease.

Normal nonpregnant women aged 20 to 35 with no history of fetal loss, thromboembolism, or autoimmune disease served as controls. None had lupus anticoagulant or anticardiolipin antibodies. Two pooled serum samples were prepared, each consisting of the sera from five different women. Commercially available IgG immune globulin (Sandoz Pharmaceuticals, East Hanover, N.J.) served as an additional control.

Immunoglobulin preparation. Immunoglobulins were precipitated from human plasma or serum with the use of 27.5% ammonium sulfate at saturation. The precipitate was dialyzed against phosphate-buffered saline solution (0.01 mol/L phosphate, pH 7.2), and the IgG fraction was separated by ion-exchange chromatography with diethylaminoethyl cellulose (Pharmacia, Uppsala, Sweden) or affinity chromatography with protein G (Pharmacia). For those fractions separated by ion-exchange chromatography, IgG was further purified by exclusion chromatography with polyacrylamide gel (Sephacryl S-300; Pharmacia). The fractions were dialyzed against phosphate-buffered saline solution and concentrated by anisotropic ultrafiltration. The purity of the IgG was determined by agarose gel electrophoresis; all samples demonstrated a single band of IgG (Fig. 1). The concentration of IgG was determined by a nephelometric method with monoclonal antihuman IgG performed on the Beckman Array System (Beckman Instruments, Brea, Calif.).

Each fraction used in these experiments was tested for endotoxin with a *Limulus* lysate assay (E-Toxate, Sigma Chemical Co., St. Louis). All fractions had <0.5 endotoxin units per milliliter.

Mouse model. Virgin BALB/c (BALB/cAnN; Charles River Laboratories, Wilmington, Mass.) mice were obtained at 10 to 15 weeks of age and maintained in the University of Utah Vivarium with food and water as desired. For mating, previously isolated male animals were placed overnight with previously isolated female animals in a ratio of 1:1. The presence of a coital plug was taken to indicate probable pregnancy (day 1). A diagnosis of pregnancy was confirmed when a mouse achieved a weight gain of ≥12% above her nonpregnant weight by day 8 after coitus.

On day 8 of pregnancy, each animal received a single intraperitoneal injection of 15 mg of IgG, either antiphospholipid antibody IgG or control. The total volume injected was approximately 1 ml, adjusted slightly to ensure an equivalent dose of IgG. We chose to use 15 mg of IgG for these experiments because we had previously found that this dose of antiphospholipid antibody IgG would result in moderate to high levels of anticardiolipin antibodies in mouse serum, mimicking the levels found in women with the antiphospholipid antibody syndrome. Peak activity appeared in the mouse serum on the second day after injection and persisted for 3 to 4 days. The mice were put to death on day 15 of pregnancy or earlier if obvious abortion ensued. For each animal the uterus was inspected under a dissecting microscope for the presence of live fetuses, dead fetuses, or resorptions. About 20% of the mice that were put to death showed no evidence of pregnancy; the uterus was non-pregnant in appearance and had a normal-appearing uterine lining when opened. In questionable cases the presence or absence of pregnancy was determined by histologic examination of the uterus. The nonpregnant animals were excluded from analysis.

The uterus was removed from 17 mice treated with antiphospholipid antibody IgG, five normal IgG-treated mice, and three saline solution controls and fixed in formalin for hematoxylin and eosin staining. Portions of the uterus and kidney from two mice treated with antiphospholipid antibody IgG from two different patients (patients 2 and 3) and one mouse treated with control IgG were snap frozen with liquid nitrogen and stored in OCT compound (Miles Laboratories, Elkhart, Ind.) for immunofluorescent studies. Tissues for immunofluorescent studies were taken 18 to 24 hours after injection of the IgG. Direct immunofluorescent staining for human IgG, fibrinogen, and the third component of complement (C3) was per-

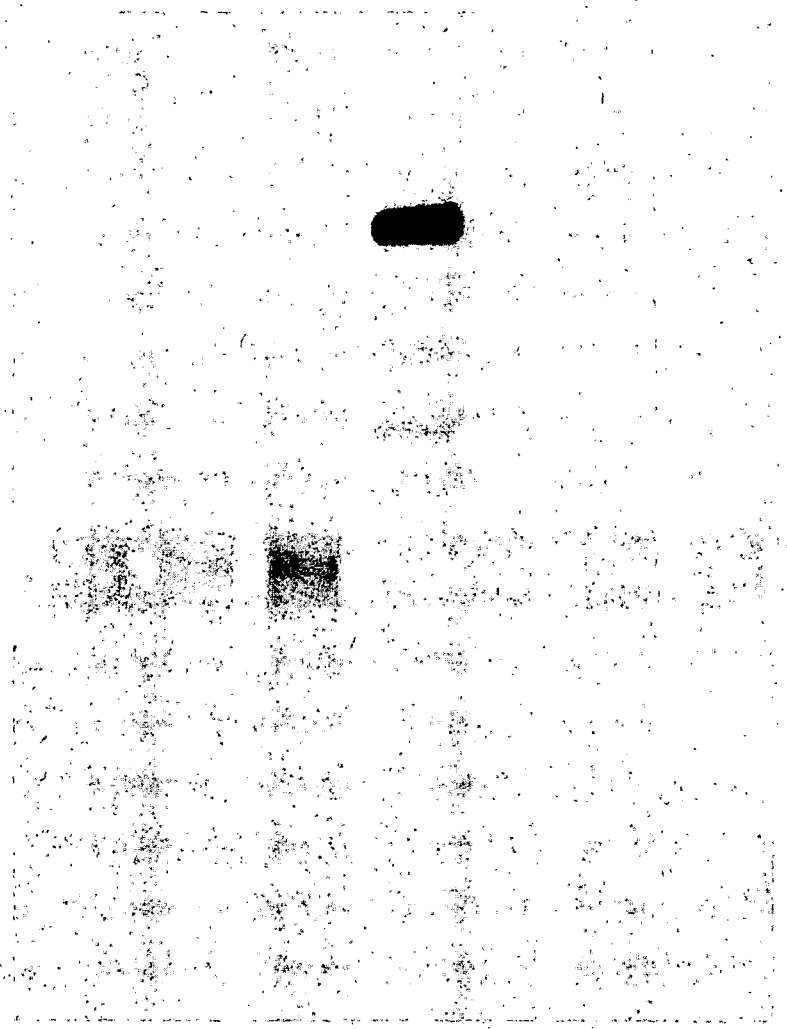

Fig. 1. High-resolution agarose gel electrophoresis of IgG fractions. A sample prepared from pooled control sera is shown in the three lanes on the left. The middle lane is whole normal serum. A sample prepared from the serum of a patient with antiphospholipid antibody syndrome is shown in the three lanes on the right.

formed according to published techniques.[5] Experienced pathologists (T. M. A. or E. H. H.) interpreted the histologic and immunofluorescent preparations in a blinded fashion.

To prove that the low concentrations of endotoxin present in our IgG fractions were not the cause of fetal loss, seven pregnant mice were given endotoxin at doses of 0.5 U (n = 4) or 1.0 U (N = 3) (*Escherichia coli* lipopolysaccharide, Sigma Chemical Co.) by intraperitoneal injection on day 8 of pregnancy. When animals were put to death on day 15 of pregnancy, normal numbers of live fetuses were found in all animals tested.

Results

Table I shows the IgG concentration, activated partial thromboplastin time, and anticardiolipin antibody levels of the IgG fractions prepared for passive immunization of the mice. Although each of the patients with antiphospholipid antibody syndrome had lupus anticoagulant demonstrated on several occasions, only the most concentrated IgG fraction (patient 1), showed a prolonged activated partial thromboplastin time indicative of lupus anticoagulant activity. The failure of the other fractions to demonstrate lupus anticoagulant activity may be due to lower concentrations of IgG, and therefore lupus anticoagulant, in the purified fractions than in the original patient plasmas. Alternatively, lupus anticoagulant activity may be due to an antibody removed by the IgG purification process, such as an IgM. All patients with the syndrome had significant levels of anticardiolipin antibodies measurable in their respective IgG fractions (range 50 to >100 IU). These levels are typical of those found in the sera

of patients with well-defined antiphospholipid antibody syndrome. As expected, all control fractions were negative for lupus anticoagulant and significant levels of anticardiolipin antibodies.

Table II shows the pregnancy outcomes for the IgG-treated mice. Saline solution–injected control animals are included for comparison. The number of live fetuses and resorptions did not differ between the groups treated with control IgG fractions. Furthermore, none of the control groups was statistically different from the mice injected with saline solution. Most important, each of the pregnant mice treated with control IgG fractions had live fetuses found when animals were put to death, with the number of live fetuses ranging from 4 to 10.

In contrast, all mice treated with antiphospholipid antibody IgG had complete fetal loss. Considering the antiphospholipid antibody IgG patient fractions separately, the number of mice with complete fetal loss was significantly different ($p < 0.05$, Fisher's exact test) from that of any control group for fractions from patients 1, 2, and 3. The number of mice treated with the fractions from patients 4 and 5 was too small to achieve statistical significance. Typically, obvious abortion began within 24 to 48 hours of passive immunization. In these cases the animals were put to death immediately. The total number of fetuses present could not be determined with accuracy in these animals because the aborted tissues were lost in the cage or ingested by the mothers. However, in all suspicious cases the presence of trophoblast was confirmed by histologic examination.

Table III shows the results of decreasing doses of antiphospholipid antibody IgG from patient 4. Doses of 1, 2, and 4 mg of the IgG fraction did not result in complete fetal loss. In the five mice treated with 8 mg of IgG, a single fetus was found alive on day 15 of pregnancy. In that same mouse there were seven resorbing fetuses found. In mice treated with doses of the IgG >8 mg, all fetuses were lost.

Twenty-three of the 25 uterine specimens fixed in formalin proved adequate for histologic examination of the uteroplacental junction. Because of obvious abortion, most of the antiphospholipid antibody IgG–treated mice were put to death on days 8 to 10 of pregnancy. At this time in gestation, the trophoblast forms a small portion of the uteroplacental interface, while the decidua is relatively prominent. Moderate to severe decidual necrosis was found in decidua taken from 14 of the 17 mice (82%) treated with antiphospholipid antibody IgG. Moderate or no decidual necrosis was found in the decidua of the five mice treated with control IgG, and no decidual necrosis was found in the decidua of the two saline solution–injected mice.

Direct immunofluorescent studies were performed on tissues from two mice treated with antiphospholipid antibody IgG and a control. The tissues taken from the mouse treated with antiphospholipid antibody IgG from patient 2 stained strongly positive for human IgG (Fig. 2). Staining for fibrin also was positive, while staining for C3 was negative. The uterine tissues taken from the mouse treated with antiphospholipid antibody IgG

Table I. Total IgG concentration, activated partial thromboplastin time, and anticardiolipin antibody levels of IgG fractions

Fraction	*Total IgG (mg/ml)*	*Dilute partial thromboplastin time* (sec)*	*Anticardiolipin antibody level† (IU)*
IgG fractions from patients with antiphospholipid antibody syndrome			
1	20.6	111	>100
2	11.7	27	50
3	18.2	38	>100
4	15.1	33	81
5	15.0	44	79
IgG fractions from controls			
1	12.7	45	<15
2	11.7	43	<15
Commercial IgG	12.0	40	<15

The fractions were prepared from patients with antiphospholipid antibody syndrome and from controls.

*In our coagulation laboratory an abnormally prolonged activated partial thromboplastin time is ≥ 48 seconds, indicating lupus anticoagulant activity.

†A value ≥ 20 IU is considered significant.[2]

Table II. Pregnancy outcome in mice treated with antiphospholipid antibody IgG or control IgG fractions

IgG fraction	*No. of mice*	*Living fetuses*	*Resorptions*
Antiphospholipid antibody IgG			
Patient 1	10	0*	†
Patient 2	7	0*	†
Patient 3	6	0*	†
Patient 4	5	0	†
Patient 5	2	0	†
Controls			
Pooled IgG			
Fraction 1	10	73	6
Fraction 2	7	57	10
Commercial IgG	8	63	6
Saline solution	17	117	10

Mice were put to death on day 15 of pregnancy or earlier if obvious abortion ensued. Saline solution–injected controls (1 ml volume) are shown for comparison

*$p < 0.05$, compared with any control group.

†The total number of fetuses was impossible to determine with accuracy because many of the animals aborted within 48 hours of passive immunization, as evidenced by vaginal bleeding and the passage of tissues in the cage. Because these tissues were often lost or eaten, an accurate count of the number of fetuses could not be performed.

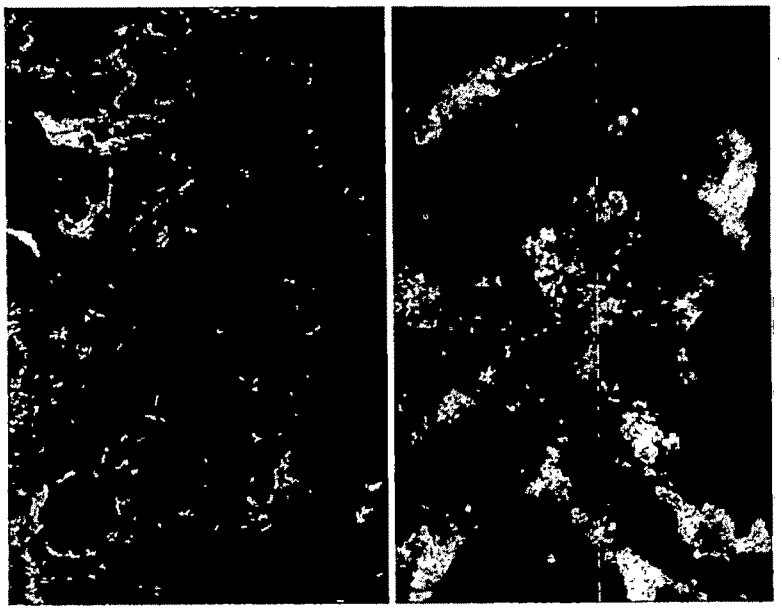

Fig. 2. Antihuman IgG immunofluorescence of mouse decidua. Decidua from a mouse treated with control IgG is shown on the left. (Original magnification × 100.) Decidua from a mouse treated with IgG from a patient with antiphospholipid antibody syndrome is shown on the right at a slightly greater magnification so that the cordlike details of the staining can be appreciated. (Original magnification × 250.)

Table III. Pregnancy outcome with different doses of antiphospholipid IgG fraction

Total IgG administered (mg)	*No. of mice*	*Living fetuses*	*Average live fetuses per mouse*
15	5	0	—
10	3	0	—
8	5	1	<1
4	5	20	4
2	4	21	5.3
1	3	18	6

The mice were treated with different doses of purified IgG from a patient with antiphospholipid antibody syndrome (patient 4). Animals were put to death on day 15 of pregnancy or earlier if obvious abortion ensued.

from patient 3 also were positive for human IgG and fibrin but less so than those taken from the mouse treated with antiphospholipid antibody IgG from patient 2. The cordlike distribution of the immunofluorescence in these decidual tissues strongly suggests intravascular staining. Tissues taken from the mouse treated with control IgG were negative for human IgG, fibrin, and C3.

Comment

Lupus anticoagulant and anticardiolipin antibodies are closely related autoantibodies that bind to phospholipid antigens. Lupus anticoagulant is identified in plasma because it prolongs phospholipid-dependent coagulation tests by binding to the phospholipid portion of the prothrombinase complex.[6] However, the *lupus anticoagulant* is clearly a misnomer because the antibody is associated with thrombosis, not bleeding.[1] Anticardiolipin antibody is identified in plasma or serum by immunoassays that use the phospholipid cardiolipin in the solid phase.[2, 4] There is a strong correlation between moderate to high levels of anticardiolipin antibody and the presence of lupus anticoagulant,[1, 7] and both antibodies are associated with the same clinical features. The risk of antiphospholipd antibody syndrome features probably increases with the level of anticardiolipin antibody.[8]

Fetal loss was first associated with the antiphospholipid antibodies in 1975 when Nilsson et al.[9] reported a case of a woman with lupus anticoagulant, thrombosis, and recurrent fetal deaths. Since then, numerous case reports and series have substantiated the relationship between antiphospholipid antibodies and fetal loss.[10-19] In fact, recent work suggests that antiphospholipid antibodies are the "cause" of pregnancy loss in 5% to 10% of women with recurrent pregnancy loss.[1]

In spite of the strong association with fetal loss, there has been no direct evidence that antiphospholipid antibody, or any other immunoglobulin, is causative. This study, with BALB/c mice, is the first to show that immunoglobulin(s) present in the IgG fraction of women with antiphospholipid antibody syndrome actually causes pregnancy loss. The results of our study are dramatic, with every mouse treated with high doses of

antiphospholipid antibody IgG fraction having complete fetal loss. Dose-response analysis demonstrates that lower doses of IgG fraction containing antiphospholipid antibodies are compatible with fetal survival. Fetal loss in this model does not appear to be due to a type III immune reaction because of the rapid time from treatment to loss and because the control mice did not suffer fetal loss, even after 7 days. Additionally, the fetal loss is not likely due to immune complexes since no complexes were found by high-resolution agarose gel electrophoresis.

There is limited information regarding the pathophysiologic features of antiphospholipid antibody–associated pregnancy loss, all from studies in the human. The fetal losses appear to be caused by a necrotizing decidual vasculopathy associated with decidual necrosis.[1, 10, 19, 20] These events, on the maternal side of the uteroplacental circulation, suggest that the transplacental passage of antibody is not necessary for fetal damage or death. Our findings in mice support the view that the pathophysiologic features of antiphospholipid antibody–associated pregnancy loss are focused on the maternal side of the uteroplacental circulation in the decidua.

In the human the decidual vasculopathy is characterized predominantly by arteriolar fibrinoid necrosis with surrounding decidual necrosis and infiltration of the vascular wall by cells with clear or foamy cytoplasm ("atherosis").[10] Our tissue preparation did not allow a detailed examination of the vasculature because the vessels of the mouse decidua are very small. However, prominent decidual necrosis was observed in more than 80% of the mice treated with antiphospholipid antibody IgG. This finding supports our model for further investigation of antiphospholipid antibody–associated pregnancy loss.

The mechanism by which antiphospholipid antibody IgG might result in decidual vasculopathy is unknown but is presumed to be the same mechanism that results in the high rate of thromboembolic disease in patients with antiphospholipid antibodies. The impressive finding of fibrin deposition in the decidua of two mice treated with antiphospholipid antibodies supports this hypothesis. One authority has proposed that antiphospholipid antibodies cause thrombosis by binding to platelet membranes and promoting platelet activation and aggregation.[21] Patients with antiphospholipid antibody syndrome may have thrombocytopenia, and platelet-associated immunoglobulin is frequently elevated in patients with the syndrome.[21] This proposed mechanism is particularly attractive in the context of our findings because the mouse decidua is rich in intravascular platelets.[22]

In summary, we have shown that purified immunoglobulin(s) from women with antiphospholipid antibody syndrome causes fetal loss in normal pregnant BALB/c mice. In this model, as in the human, decidual necrosis is a feature of fetal loss. Our studies suggest that the necrosis is due to immunoglobulin-mediated intravascular damage with deposition of fibrin clot. In the future our mouse model will be used to explore the pathophysiologic details of fetal loss and to investigate existing and new treatments for pregnancies complicated by antiphospholipid antibodies.

In vitro effect of RU 486 on sperm-egg interaction in mice

Subhash C. Juneja, PhD, and Melvin G. Dodson, MD, PhD

Johnson City, Tennessee

The effect of RU 486 at different concentrations (1, 5, 10, and 20 μg/ml) was studied on sperm-egg interaction in vitro in B6D2F1 mice. The in vitro fertilization rate of mouse ova decreased from 77.0% (control) to 50.0%, 28.7%, and 7.5% in the presence of RU 486 concentrations at 5, 10, and 20 μg/ml medium, respectively ($p < 0.001$). A concentration of 1 μg/ml did not affect the fertilization rate. A progesterone concentration at equal to or double the concentration RU 486 did not reverse the inhibitory effect of RU 486 on in vitro fertilization, which suggests a progesterone-independent mechanism. Exposure of spermatozoa (for 90 minutes) or ova (for 60 minutes) to RU 486 (20 μg/ml) followed by washing with RU 486–free medium before coincubation did not affect the fertilization rate. The presence or absence of cumulus cells did not change the inhibitory effect of RU 486 (20 μg/ml) on in vitro fertilization. RU 486 at 5 to 20 μg/ml medium was associated with perivitelline polyspermy in nonfertilized ova and enhanced perivitelline polyspermy in fertilized ova. (Am J Obstet Gynecol 1990;163:216-21.)

Key words: RU 486, in vitro fertilization, perivitelline polyspermy, vitellus block

RU 486 [17β-hydroxy-11β-(4-dimethylaminophenyl)-17α-(1-propynyl)estra-4,9-dien-3-one] is an antiprogestin steroid. At the molecular level, RU 486 is thought to stabilize the complex formed by the progesterone receptor and the heat-shock protein hsp90, which in turn blocks the deoxyribonucleic acid–binding site of the progesterone receptor and precludes a hormonal response.[1] In vitro, RU 486 causes a reduction in the synthesis of human placental chorionic gonadotropin (hCG), human placental lactogen (hPL), and progesterone by syncytiotrophoblast cells.[2] Treatment of rats, mice, and rabbits with RU 486 during early pregnancy blocks decidualization of the endometrium and inhibits implantation.[3,4] Cullingford and Pollard[5] noted complete inhibition of cell proliferation in the mouse uterus by RU 486. Recently, RU 486 has been used as an abortifacient in women.[6,7] It has also been used to enhance cervical ripening[8,9] and to facilitate the delivery of dead fetuses.[10] The antiprogesterone activity of RU 486 has been thought to be responsible for these biologic activities. RU 486 is potentially an important new drug with multiple uses in gynecology. However, the full effect on reproductive function is still being investigated.

This study reports the effects of RU 486 on fertilization in vitro in the mouse.

Material and methods

Superovulation of mice. Male and female B6D2F1 mice (Charles River Labs., Raleigh, North Carolina) were housed at 23° to 25° C under controlled illumination (14 hours light and 10 hours darkness). Water and pelleted food were supplied at will. Female mice (weight 20 to 25 gm, 7 to 8 weeks old) were superovulated with 7 IU pregnant mare's serum gonadotropin (PMSG) (Sigma Chemical Co., St. Louis) intraperitoneally followed 48 hours later by 7 IU of hCG (Sigma). At 14 hours after hCG injection, mice were sacrificed by cervical dislocation, the oviducts were removed, and cumulus masses were collected in culture medium. Cumulus masses from different mice were pooled and

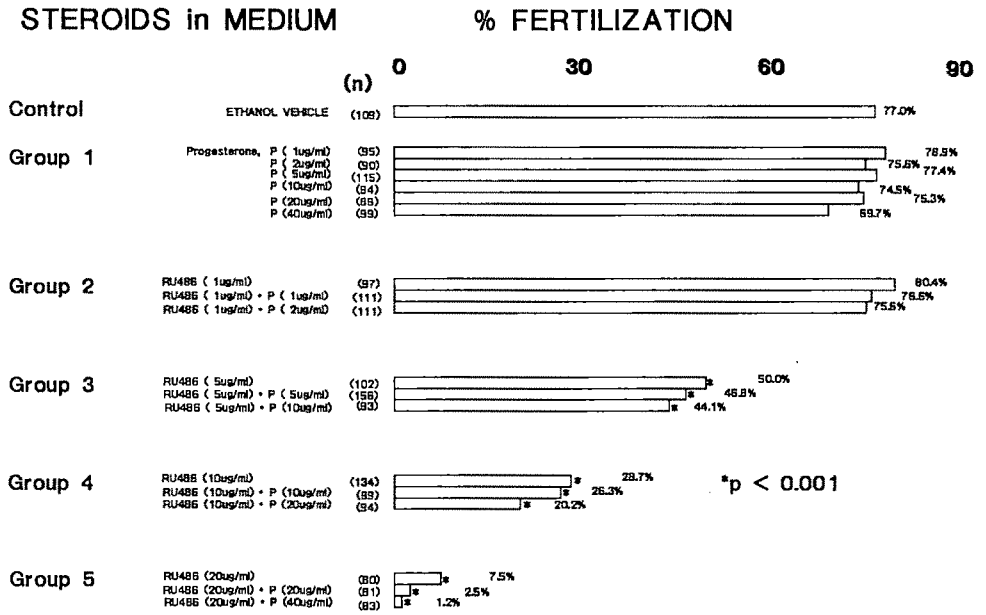

Fig. 1. Effect of RU 486 on in vitro fertilization in mice. The dose-dependent decrease of in vitro fertilization that is shown at concentrations of RU 486 from 5 to 20 μg/ml (groups 2 to 5) is not reversed by equal or double the concentration of progesterone; progesterone (group 1) causes a nonsignificant decrease in fertilization rate.

distributed randomly into 24-cell plates with 0.4 ml of culture medium in each well.

Sperm collection and capacitation. Mature male mice (age >12 weeks) were sacrificed 12½ hours after hCG injection of female mice, and the caudae epididymides were excised. Spermatozoa were released by rupturing the caudae epididymides with fine forceps. Spermatozoa were capacitated for 90 minutes at 37° C in capacitation medium at 5% carbon dioxide and 95% air in a humidified incubator and washed by centrifugation at 800 *g* for 15 minutes before insemination.

In vitro fertilization. Ova (14 to 14½ hours after hCG) were incubated with spermatozoa at a concentration of 100,000 sperm/ml for 3 hours at 37° C at 5% carbon dioxide in a humidified incubator, washed, transferred into culture medium, incubated, and assessed for fertilization after 8 to 10 hours. Embryos were stained with a fluorescent deoxyribonucleic acid–binding dye (Hoechst 33258, Sigma) as previously reported[11] and examined with a fluorescence microscope. The presence of a second polar body, the resumption of second meiotic division, and the presence of a cytoplasmic decondensing sperm head or two pronuclei were considered evidence of fertilization.

Medium. Culture medium consisted of Ham's F-10 (Sigma) supplemented with 3 mg of bovine serum albumin (fraction V, Sigma). Capacitation medium was supplemented with bovine serum albumin 30 mg/ml and equilibrated at 37° C with a 5% carbon dioxide atmosphere for 12 hours before use.

Steroid solutions. RU 486 (Roussel-Uclaf, Raminville, France) and progesterone (Sigma) were solubilized in ethanol. The concentration of ethanol in both treatment and control groups was 0.1%. Since the steroids are lipophilic, medium was not overlaid with oil.

In vitro experiments. The effect of RU 486 on in vitro fertilization was evaluated at concentrations from 1 to 20 μg/ml. Cultures were supplemented with progesterone at concentrations equal to or double the concentration of RU 486. Control cultures of progesterone were evaluated at concentrations from 1-40 μg/ml. Each experiment represents three replicates.

The effect of RU 486 (20 μg/ml) on spermatozoa was evaluated after 90 minutes of exposure in medium. Spermatozoa were washed in RU 486–free medium followed by centrifugation before insemination.

The effect of RU 486 (20 μg/ml) on ova before insemination was evaluated by preincubating the cumulas masses with RU 486 in medium for 1 hour.

The effect of RU 486 (20 μg/ml) on the in vitro fertilization of cumulus-free ova (cumulus treated with 0.1% hyaluronidase, Sigma) and cumulus-enclosed ova was compared.

Data were analyzed by 2 × 2 χ^2 contingency tables.

Results

RU 486 inhibited in vitro fertilization in a dose-response manner in mice at concentrations from 5 to 20 μg/ml (Fig. 1). An RU 486 concentration of 1 μg/ml did not affect fertilization. In vitro fertilization

Table I. In vitro fetilization when gametes were treated with RU 486 before coincubation

Attribute	*% Fertilization*	*n*
Sperm capacitated in presence of RU 486 (20 μg/ml)	77.7	193
Control	71.5	158
Cumulus treated with RU 486 (20 μg/ml) for 1 hr before insemination	78.9	95
Control	80.1	116

Table II. Effect of RU 486 on in vitro fertilization in the presence or absence of the cumulus

Attribute	*% Fertilization*	*n*
Fertilization of cumulus-free ova in presence of RU 486 (20 μg/ml)	5.1%*	78
Control (cumulus-free)	88.0%	75
Fertilization of cumulus-enclosed ova in presence of RU 486 (20 μg/ml)	5.9%†	84
Control (cumulus-enclosed)	82.2	107

The cumulus-free and cumulus-enclosed rates did not differ from each other, nor did the control rates.

*Significantly different from control (cumulus-free) ($p < 0.001$).

†Significantly different from control (cumulus-enclosed) ($p < 0.001$).

rates of mouse ova decreased from 77.0% (control) to 50.0%, 28.7%, and 7.5% in the presence of RU 486 concentrations at 5, 10, and 20 μg/ml medium, respectively. Progesterone (1 to 40 μg/ml) did not significantly affect fertilization in vitro (group 1, Fig. 1), although there was a consistent nonsignificant decrease in fertilization rates noted in all experimental groups in the presence of progesterone at higher concentrations. The addition of progesterone at equal to or double the concentration of RU 486 did not reverse the inhibitory effect of RU 486 at 5 μg/ml (group 3), 10 μg/ml (group 4), or 20 μg/ml (group 5) on in vitro fertilization (Fig. 1).

Spermatozoa capacitated in the presence of RU 486 for 90 minutes at a concentration of 20 μg/ml followed by washing in RU 486–free medium did not alter the fertilization capability of the spermatozoa compared with that of control spermatozoa capacitated in RU 486–free medium (Table I). Likewise, exposure of ova to RU 486 (20 μg/ml) before insemination followed by washing of the ova in RU 486–free medium did not alter the quality of ova as reflected by fertilization (Table I).

The presence or absence of cumulus cells did not alter the inhibitory effect of RU 486 on in vitro fertilization (Table II). The fertilization rate of either cumulus-free or cumulus-enclosed ova in the presence of RU 486 (20 μg/ml) was significantly depressed compared with fertilization in RU 486–free medium ($p < 0.001$) but was not significantly different (5.12% vs 5.95%) between each other (cumulus-free vs cumulus-enclosed).

Fig. 2. Perivitelline polyspermy in unfertilized ova under the influence of RU 486 (20 μg/ml). Three spermatozoa and the first polar body are visible in perivitelline space; two spermatozoa are attached to zona pellucida.

In ova that did not fertilize in the presence of RU 486, there was a progressive increase in the number of spermatozoa with increased concentrations of RU 486 that had penetrated the zona pellucida but not the vitelline membrane. Frequently, multiple spermatozoa (one to nine) collected in the perivitelline space (Fig. 2). No sperm were noted in the perivitelline space of control ova, which did not fertilize in RU 486–free medium (Fig. 3). There were no sperm in the perivitelline space in ova that did not fertilize in the presence of RU 486 at a concentration of 1 μg/ml. The number of unfertilized ova with multiple spermatozoa in the perivitelline space increased from 0.0% (control) to 58.8% at 5 μg/ml, 75.0% at 10 μg/ml, and 72.9% at 20 μg/ml concentrations of RU 486 ($p < 0.001$, Fig. 3).

Perivitelline polyspermy among fertilized ova increased from 10.7% (control) to 54.9%, 73.6%, and 83.3% at RU 486 concentrations of 5, 10, and 20 μg/ml, respectively ($p < 0.001$, Fig. 4). From one to eight sperm collected in the perivitelline space of fertilized ova. An RU 486 concentration at 1 μg/ml did not affect the perivitelline polyspermy in fertilized ova.

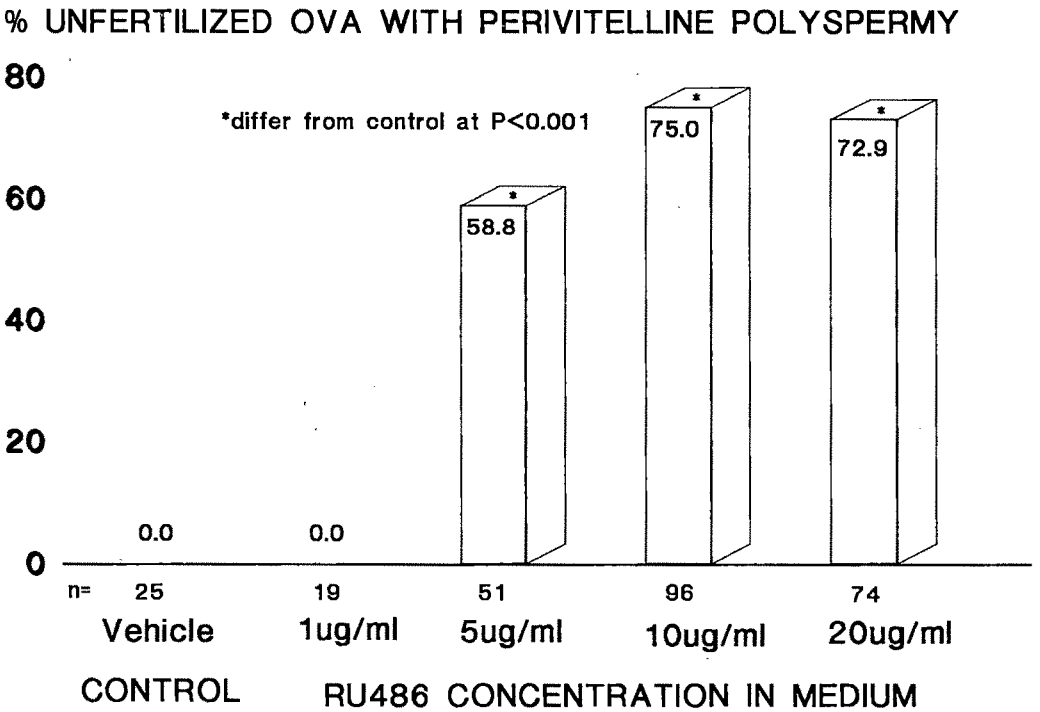

Fig. 3. A dose-dependent increase in perivitelline polyspermy is noted in unfertilized ova under the influence of RU 486.

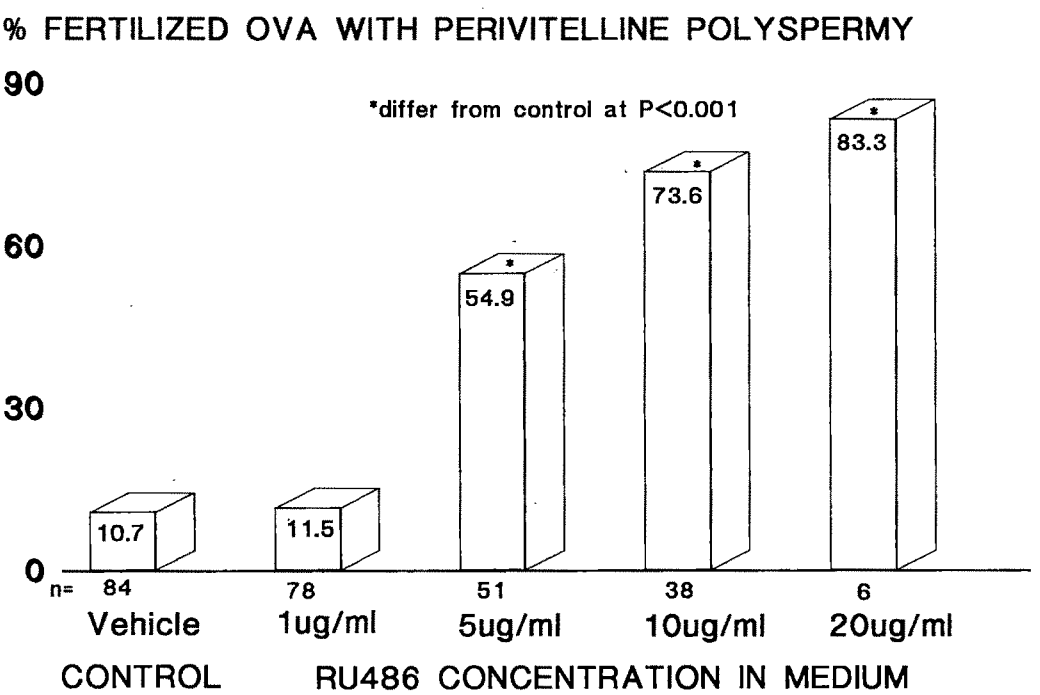

Fig. 4. A dose-dependent increase in perivitelline polyspermy is noted in fertilized ova under the influence of RU 486.

Comment

The presence of RU 486 resulted in a dose-dependent decrease in fertilization of mouse ova in vitro. The effect does not appear to result from a toxic effect on either the spermatozoa or ova alone, since the exposure of spermatozoa or ova to RU 486 (sperm 90 minutes; ova 60 minutes) followed by washing did not decrease the in vitro fertilization rate even

at a concentration of 20 μg/ml. It was necessary for RU 486 to be present during coincubation of ova and spermatozoa before fertilization was noted to decrease. Concentrations of ≥5 μg/ml were necessary to demonstrate the inhibitor effect of RU 486 on in vitro fertilization. The inhibitory effect of RU 486 on in vitro fertilization could not be reversed by the presence of progesterone at equal to or twice the concentration (in micrograms per milliliter) of RU 486. Most of the biologic effects of RU 486 are thought to be mediated through its antiprogestin action. However, the lack of reversibility of RU 486 on the inhibition of in vitro fertilization in the presence of progesterone suggests that either the inhibition of fertilization is mediated through a progesterone-independent mechanism or the binding of RU 486 to the progesterone receptor is nonreversible in the presence of progesterone at equal to or double the concentration used in this study. The inhibitory effect of RU 486 on human syncytiotrophoblast production of hCG, hPL, and progesterone has previously been reported to be reversed by the addition of exogenous progesterone.[2] However, a lower concentration of RU 486 than in our study was used to support syncytiotrophoblast hormone production, and a tenfold concentration of progesterone was used to reverse the inhibitory effect.[2]

In humans, RU 486 has been shown to inhibit granulosa cell progesterone production.[12] Progesterone, however, has not been shown to be necessary for fertilization in vitro. In fact, in this study we noted a tendency for decreased fertilization at high progesterone concentrations. However, this trend was not statistically significant. In this study RU 486 inhibited fertilization in the presence or absence of cumulus cells (Table II).

In mice and several other species, including the human and hamster, acrosome-intact capacitated sperm bind to a glycoprotein (ZP3) on the surface of the zona pellucida.[13-16] ZP3 induces the acrosome reaction, and only acrosome-reacted spermatozoa are capable of penetrating the zona pellucida and binding to the vitelline membrane.[17] Penetration of the vitelline membrane by a sperm results in fusion of the cortical granules with the plasma membrane and release of their contents (cortical reaction). Degradation of cortical granules results in the zona reaction, which in turn blocks polyspermy. However, in some strains of mice, even after the first sperm fuses with the vitelline membrane, a few additional spermatozoa continue to enter the perivitelline space.[18] Sato[18] noted penetration of the zona pellucida by one to eight spermatozoa even after a sperm had fused with the vitellus. Perivitelline polyspermy is not uncommon. In Sato's study[18] a total of 47 accessory spermatozoa were noted in the perivitelline space in 24 eggs. Most of the spermatozoa had entered the perivitelline space within 1 minute after fusion of the fertilizing sperm with the vitellus.[18] In this study we noted a dose-dependent increase in the number of unfertilized ova and zygotes with perivitelline polyspermy in the presence of RU 486. The block of polyspermic fertilization in the mouse is thought to be at the level of the zona.[19] Polyspermic fertilization occurs when capacitated and acrosome-reacted sperm successfully penetrate the zona and fuse with the vitellus. In the presence of RU 486 at concentrations of ≥5 μg/ml, multiple spermatozoal penetration of the zona occurs. However, despite the presence of multiple spermatozoa in the perivitelline space, polyspermic fertilization with penetration of the vitellus did not occur in this study. Perivitelline polyspermy was noted in 10.7% of control zygotes (Fig. 4). However, perivitelline polyspermy increased dramatically in the presence of RU 486. There was no significant difference in the degree of polyspermy in fertilized and unfertilized ova.

One possible explanation for the data presented is a block of the zona reaction in fertilized mouse ova in the presence of RU 486 that allows spermatozoa to accumulate in the perivitelline space despite fertilization. RU 486 at higher concentrations might cause inhibition of penetration of the vitelline membrane but not the zona pellucida. Another possibility is that RU 486 enhances zona penetration by spermatozoa.

The presence of multiple spermatozoa in the perivitelline space, even in unfertilized ova, also was noted at concentrations of RU 486 of 5 to 20 μg/ml. Since no sperm had penetrated the plasma membrane and fertilized the ova, the release of the cortical granules and the zona reaction should not have occurred. However, RU 486 appears to allow spermatozoa to penetrate the zona but not the vitelline membrane, thereby resulting in perivitelline polyspermy but not fertilization. No zona penetration was noted in unfertilized ova in the absence of RU 486 or at a concentration of 1 μg/ml. Whether spermatozoa that penetrate the zona under the influence of RU 486 are acrosome-reacted is under investigation.

In conclusion, RU 486 inhibits fertilization in vitro in a dose-dependent manner that is not reversed by twice the concentration of progesterone. The decreased fertilization does not appear to result from a toxic effect on either the ova or spermatozoa and is independent of the presence of surrounding granulosa cells. Perivitelline polyspermy occurs in unfertilized and fertilized eggs in the presence of RU 486.

We thank Roussel-Uclaf, Romainville, France, for providing us with a gift of RU 486.

Relationship between the ovine fetal umbilical artery blood flow waveform and umbilical vascular resistance

Glenn L. Irion, PhD, and Kenneth E. Clark, PhD
Cincinnati, Ohio

Ultrasonic umbilical artery blood flow velocity waveform indexes decrease throughout gestation as umbilical blood flow increases. However, it is not known whether the decrease in indexes such as systolic/diastolic ratio is a direct result of a change in umbilical vascular resistance. Umbilical artery blood flow was measured as vasoactive agents angiotensin II, arginine vasopressin, norepinephrine, serotonin, and the thromboxane A_2 sympathomimetic agent U-46619 were infused into the inferior vena cava of chronically instrumented ovine fetuses. Angiotensin II, arginine vasopressin, norepinephrine, serotonin, and U-46619 all significantly increased fetal arterial pressure levels. Angiotensin II, arginine vasopressin, and U-46619 significantly reduced umbilical blood flow and fetal heart rate. All five pressor agents increased umbilical vascular resistance. Systolic/diastolic ratios were obtained from pulsatile umbilical blood flow tracings. Systolic/diastolic ratios before infusions were significantly correlated with baseline values of umbilical blood flow ($r = -0.55$) and umbilical vascular resistance ($r = 0.52$). Systolic/diastolic ratios decreased with increasing infusion rates of angiotensin II, arginine vasopressin, norepinephrine, and serotonin, and increased with infusion of U-46619. There was no significant correlation between systolic/diastolic ratio and either umbilical blood flow or umbilical vascular resistance during infusion of angiotensin II, arginine vasopressin, or serotonin. Systolic/diastolic ratio decreased with increasing umbilical vascular resistance during norepinephrine infusion ($r = -0.44$). Systolic/diastolic ratio changed in the predicted direction only when umbilical vascular resistance was increased by infusion of U-46619 ($r = 0.80$). We conclude that umbilical artery waveform analysis is not an adequate predictor of acute changes in umbilical blood flow or vascular resistance. (Am J Obstet Gynecol 1990;163:222-9.)

Key words: Pregnant ewe, Doppler ultrasonography, gestation

Measurement of umbilical artery blood flow velocity waveform indexes such as systolic/diastolic (S/D) ratio has been proposed as a means to noninvasively assess fetal well-being. Umbilical blood flow velocity waveform indexes decrease throughout gestation as umbilical blood flow increases and umbilical vascular resistance decreases.[1] It has been proposed that the decrease in S/D ratio is a result of a progressive increase in the size of the fetoplacental vascular bed and decreasing vascular resistance.[2] It is not known whether changes in waveforms are caused by changes in umbilical vascular resistance or whether another factor, such as increased number of vessels in the fetoplacental microcirculation, that may lead to decreases in both S/D ratio and umbilical vascular resistance, is responsible for the correlation between S/D ratio and umbilical vascular resistance.

Pathologic studies have indicted a strong relationship between waveform indexes and the number of small vessels in the placental vascular bed.[3, 4] The relationships between S/D ratio, umbilical vascular resistance, and the size of the fetoplacental vascular bed might be clarified by procedures that alter either umbilical vascular resistance or the number of fetoplacental microvessels with blood flow. Experiments with the use of embolization of the umbilical circulation with microspheres, thereby decreasing the functional size of the fetoplacental vascular bed, have not clarified these relationships.[5, 6] During a series of embolizations over a short period of time S/D ratio and umbilical vascular resistance were highly correlated,[5] whereas during a 9-day schedule of daily embolization changes in S/D ratio and umbilical vascular resistance occurred at different rates.[6] Alteration of umbilical vascular resistance pharmacologically has not clarified these relationships. Infusion of U-46619, a thromboxane A_2 sympathomimetic, into the lower aorta of sheep fetuses increased vascular resistance of the umbilical cotyledonary circulation and increased S/D ratio, whereas infusion of prostacyclin decreased S/D ratio but did not significantly alter cotyledonary vascular resistance.[7]

Previously, with the use of high frequency measurements of umbilical blood flow by means of transit-time

Doppler flow probes, we showed that S/D ratio and umbilical blood flow change with gestation in the chronically instrumented ovine fetus in a manner similar to that ascribed to human fetuses.[1] We also showed that in the ovine fetus S/D ratio and umbilical blood flow are highly correlated throughout the last trimester. In the present investigation we measured umbilical blood flow and fetal arterial pressure in chronically instrumented ovine fetuses during intravenous infusion of vasoactive agents to determine whether acute increases in umbilical vascular resistance are accompanied by increases in umbilical S/D ratios.

Methods

Surgical procedures. Nine pregnant ewes (40 to 60 kg) carrying singleton (seven) or twin (two) fetuses were instrumented during aseptic surgical procedures. Guidelines approved by the University of Cincinnati for the care and use of the animals were followed. Maternal and fetal instrumentation was performed at 105 to 110 days' gestation. In the two cases of twin pregnancies, only one fetus was instrumented. Ewes were fasted for 48 hours before surgery. On the day of surgery a diazepam preparation (Valium, 10 mg) was injected intramuscularly 30 minutes before intravenous administration of pentobarbital (15 mg/kg). Surgery was performed under pentobarbital and spinal (Pontocaine, 12 mg) anesthesia. Polyvinyl catheters were placed in the maternal distal aorta and inferior vena cava through the left femoral artery and vein. The uterus was then exposed by means of a midline incision. Through a small uterine incision, the left fetal hind limb was delivered to place polyvinyl catheters into the fetal aorta through the femoral artery and the inferior vena cava through a fetal hind limb vein. The volumes of all catheters were determined before placement.

After a left retroperitoneal incision, the fetus was marsupialized to the uterus. The area surrounding the common umbilical artery was exposed, and a 6 to 8 mm ultrasonic transit-time flow probe (Transonic Systems, Inc., Ithaca, N.Y.) was placed around the common umbilical artery, just proximal to the branches of the umbilical artery. At this location, approximately 95% of the blood flow is directed to the fetoplacental circulation. Fetal and uterine incisions were subsequently closed. Electromagnetic flow probes (Dienco, Los Angeles) were placed around both maternal middle uterine arteries. All instrumentation was passed through a subcutaneous tunnel and exteriorized through a small incision on the ewe's left flank. Catheters were flushed and filled with heparinized saline solution (1000 U/ml, maternal; 500 U/ml, fetal). Catheters and cables were kept in a canvas pouch attached to the ewe's left flank. Catheters were flushed every other day with heparinized saline solution at the above concentrations. Antibiotics were administered to the ewe and fetus. The ewe received 6 ml of Combiotic intramuscularly (Pfizer, New York) postoperatively and 6 ml doses for 3 days after surgery. The fetus received 1 gm of ampicillin (Omnipen, Wyeth, Philadelphia) through an amniotic fluid catheter postoperatively and 0.5 gm for 3 days after surgery.

Measurements. Hemodynamic recordings were made on sheep ranging from 110 to 129 days' gestation. On the experimental day sheep were allowed a period of acclimatization to experimental rooms, after which baseline measurements were obtained for 30 minutes. Vasoactive agents were dissolved in saline solution at different concentrations, each 10-fold greater than the other. Different infusion rates of the vasoactive agents could then be delivered through the fetal hind limb vein catheter with only two different infusion rates (either 0.10 or 0.30 ml/min) by an infusion pump (model 355, Sage Instruments, Cambridge, Mass.). Fetal body mass was estimated from growth curves generated in our laboratory as:

$$\text{Fetal body mass (gm)} = [(\text{Days of gestation} - 37) \cdot 0.16]^3$$

Different doses of the vasoactive substances were infused into the fetal hind limb vein in ascending order for a period of 5 minutes after the venous catheter was filled with the appropriate solutions and volume. All experiments were performed on animals with fetal $P_aO_2 \geq 18$ mm Hg and pH ≥ 7.3. Five different vasoactive substances were infused. Only one substance was used on a given day on any given sheep. The substances included angiotensin II at infusion rates of 0.1, 0.3, 1, and 3 μg/min/kg (Ciba Pharmaceuticals, Summit, N.J.); arginine vasopressin acetate at infusion rates of 1, 3, 10, 30, 100, and 300 ng/min/kg (Sigma Chemical Co., St. Louis); norepinephrine bitartrate at infusion rates of 0.3, 1, and 3 μg/min/kg (Sigma); serotonin at infusion rates of 1, 3, and 10 μg/min/kg (Sigma); and the thromboxane A_2 sympathomimetic agent U-46619 at infusion rates of 0.3, 1, 3, and 10 μg/min/kg (Cayman Chemical Co., Ann Arbor, Mich.). Complete dose-response relationships were obtained on four sheep for angiotensin II, two sheep for arginine vasopressin, three sheep for norepinephrine, three sheep for serotonin, and three sheep for U-46619.

Both pulsatile and integrated umbilical artery blood flow were recorded with model T101 Doppler ultrasonographic flowmeters (Transonic). Blood pressure was recorded with MP 15 pressure transducers (Micron Instruments, Inc., Simi Valley, Calif.) anchored at the level of the maternal sternum and attached to maternal and fetal arterial catheters. Heart rate was derived from the arterial pressure pulse by means of Sensor Medics 9857 cardiotachometer couplers (Anaheim, Calif.).

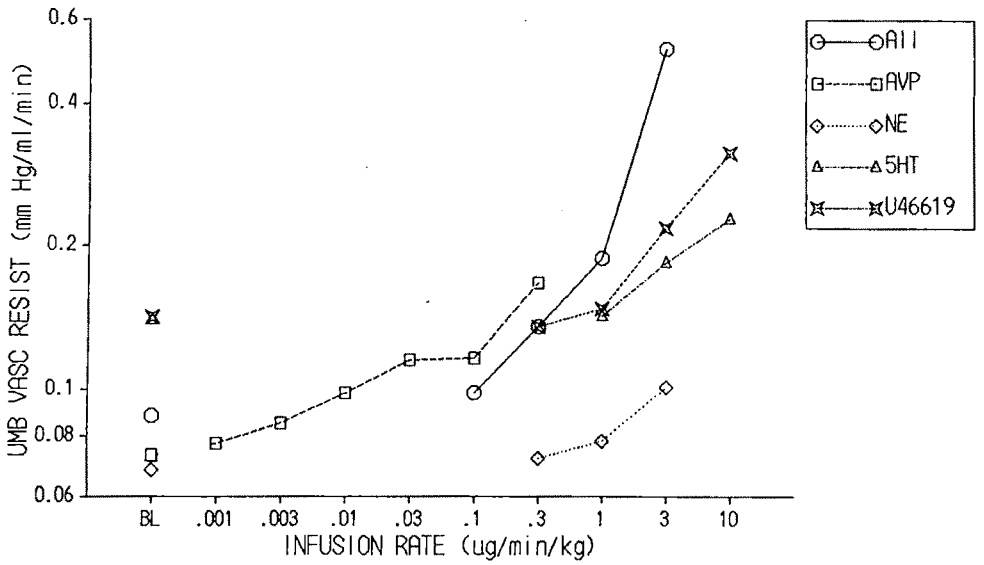

Fig. 1. Umbilical vascular resistance during infusion of angiotensin II (*AII*) ($n = 4$), arginine vasopressin (*AVP*) ($n = 2$), norepinephrine (*NE*) ($n = 3$), serotonin (*5HT*) ($n = 3$), and U-46619 ($n = 3$). All five substances significantly increased umbilical vascular resistance ($p < 0.05$). Values are means at each infusion rate plotted on log scale. Error bars are omitted for clarity.

Umbilical blood flow, fetal arterial pressure, fetal heart rate (FHR), maternal arterial pressure, maternal heart rate, and right and left uterine blood flows were recorded continuously with SensorMedics R612 recorders. Because the experiments were all conducted before the last 2 weeks of pregnancy, we did not measure amniotic fluid pressure. Therefore, vascular resistance was computed from only mean umbilical blood flow and fetal mean arterial pressure measured from the aorta, neglecting venous and amniotic pressures. Hemodynamic responses to arginine vasopressin infusion have been previously reported.[8]

Waveform analysis. Umbilical blood flow was recorded at the speed of 25 mm/second. Pulsatile recordings were obtained by setting the low-pass cutoff frequency of the flowmeter to either 30 or 100 Hz for at least 1 minute. Blood flow was also recorded at 0.1 Hz to determine umbilical blood flow averaged over the cardiac cycle. Peak systolic and minimum diastolic values were measured across a period of at least 10 to 15 seconds (10 to 20 cardiac cycles) during which systolic and diastolic values did not vary by more than 20%. S/D ratio was computed as maximum divided by minimum value of the flow wave.

Statistical analysis. Values reported were obtained near the end of the 5-minute infusion periods. In general, parameters reached a steady state during the last 2 minutes and a single value averaged over the last 2 minutes for each parameter and infusion rate in each animal was used for statistical analysis. One factor analysis of variance with repeated measures across different infusion rates of each vasoactive substance was used to determine whether any differences existed in responses to different infusion rates. Newman-Keuls posthoc analysis was then used to determine which groups were significantly different from each other ($p < 0.05$). Because values of S/D ratio may significantly differ from a gaussian distribution,[9] statistical analyses involving S/D ratio were also performed with the resistance index (RI) as RI = (systolic − diastolic)/systolic value of the waveform, the distribution of which appears to be gaussian.[9] These indexes are exactly related by the relationship RI = 1 − S/D ratio^{-1}. In this investigation S/D ratio and RI had a linear correlation coefficient of 0.97. The distribution of S/D ratio values was significantly skewed in the positive direction (skewness = 0.75, $p < 0.01$), but the distribution of RI values showed no evidence of skewness (skewness = − 0.11) and neither distribution showed any evidence of kurtosis. Results of analyses based on either S/D ratio or RI led to the same conclusions and only the S/D ratio data are shown here.

Results

No maternal hemodynamic changes were observed during infusion of any of the five vasoactive substances used in this investigation. The vasoactive agents that we infused into the fetal hind limb vein all produced dose-related increases in fetal arterial pressure ranging from 24% to 52% with different agents. Angiotensin II, arginine vasopressin, and U-46619 produced dose-related decreases in umbilical blood flow. Maximum

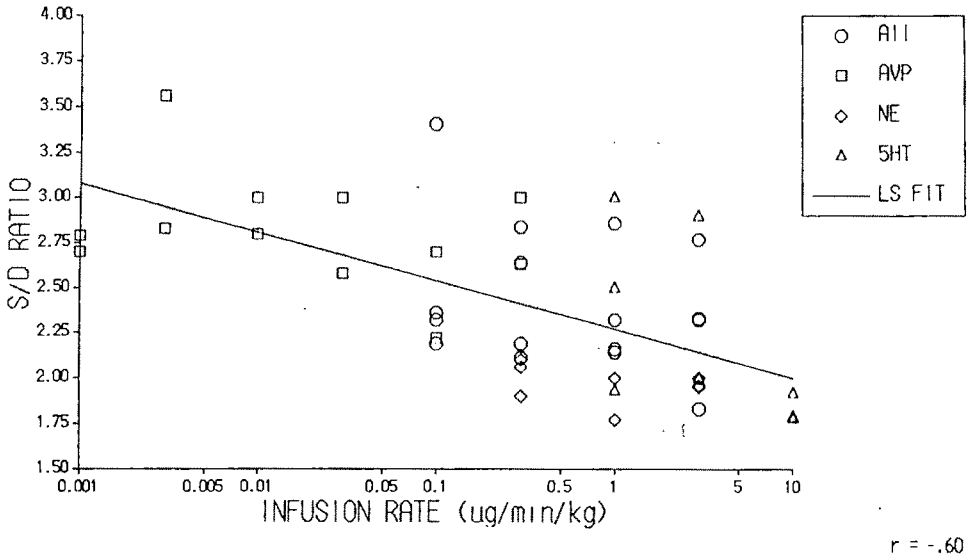

Fig. 2. Relationship between S/D ratio and infusion rate of angiotensin II (*AII*) ($n = 4$ sheep · 4 doses), arginine vasopressin (*AVP*) ($n = 2$ sheep · 6 doses), norepinephrine (*NE*) ($n = 3$ sheep · 3 doses), and serotonin (*5HT*) ($n = 3$ sheep · 3 doses). S/D ratio decreased significantly with increasing infusion rate ($r = -0.60$, $n = 46$, $p < 0.01$). Line is least squares fit of data.

decreases were 74%, 34%, and 34%, respectively. FHR also decreased with infusion of angiotensin II, arginine vasopressin, and U-46619 by a maximum of 15%, 42%, and 37% with these three agents, respectively. No significant changes in umbilical blood flow or FHR could be observed with infusion of norepinephrine or serotonin. All five agents significantly increased umbilical vascular resistance in a dose-related fashion (Fig. 1). Because of the number of observations, clear relationships between dose and S/D ratio for each pressor agent could not be shown. However, by pooling the data from angiotensin II, arginine vasopressin, norepinephrine, and serotonin, a significant correlation between S/D ratio and log infusion rate could be observed ($r = -0.60$, $p < 0.01$) (see Fig. 2).

Before infusion of vasoactive agents the baseline S/D ratios that we recorded were significantly correlated to both umbilical blood flow ($r = -0.55$, $p < 0.01$) (Fig. 3) and umbilical vascular resistance ($r = 0.52$, $p < 0.01$) (Fig. 4). S/D ratio changed as would be expected if S/D ratio were a predictor of umbilical vascular resistance only during infusion of the thromboxane A_2 sympathomimetic agent U-46619; S/D ratio increased as umbilical vascular resistance increased ($r = 0.80$, $p < 0.01$) (Fig. 5, *E*). However, S/D ratio did not increase as umbilical vascular resistance increased during infusion of the other four vasoactive agents. There was no correlation between S/D ratio and umbilical vascular resistance during infusion of angiotensin II, arginine vasopressin, or serotonin (Fig. 5, *A, B, C,*), and during infusion of norepinephrine, S/D ratio decreased as umbilical vascular resistance increased ($r = -0.44$, $0.05 < p < 0.10$) (Fig. 5, *D*). During these acute changes in umbilical vascular resistance, the relationship between S/D ratio and umbilical vascular resistance observed before infusions was not maintained for all five pressors.

Umbilical artery waveform values have been shown to be inversely correlated to FHR, at least within a range of FHRs.[1, 10, 11] Overall, in the present investigation S/D ratio was also significantly correlated to heart rate ($r = -0.38$, $p < 0.5$), although the relationship differed with infusion of different drugs. Correlation coefficients between S/D ratio and heart rate were -0.09, 0.02, -0.38, -0.22, and -0.39 for angiotensin II, arginine vasopressin, norepinephrine, serotonin, and U-46619, respectively. None of these correlation coefficients reached a significance level of $p < 0.05$ for the number of observations. The effect of heart rate on S/D ratios did not appear to affect the relationship between umbilical vascular resistance and S/D ratio. Analysis by multiple linear regression with the use of both heart rate and vascular resistance as predictors of S/D ratio did not reveal any significant relationships except for U-46619 ($r^2 = 0.46$). This value was similar to that found for umbilical vascular resistance alone. Moreover, heart rate and umbilical vascular resistance were significantly related to each other during infusion of the vasoactive substances, substantially reducing the validity of this analysis. Heart rate decreased as umbilical vascular resistance increased during infusion of angiotensin II, arginine vasopressin, and U-46619

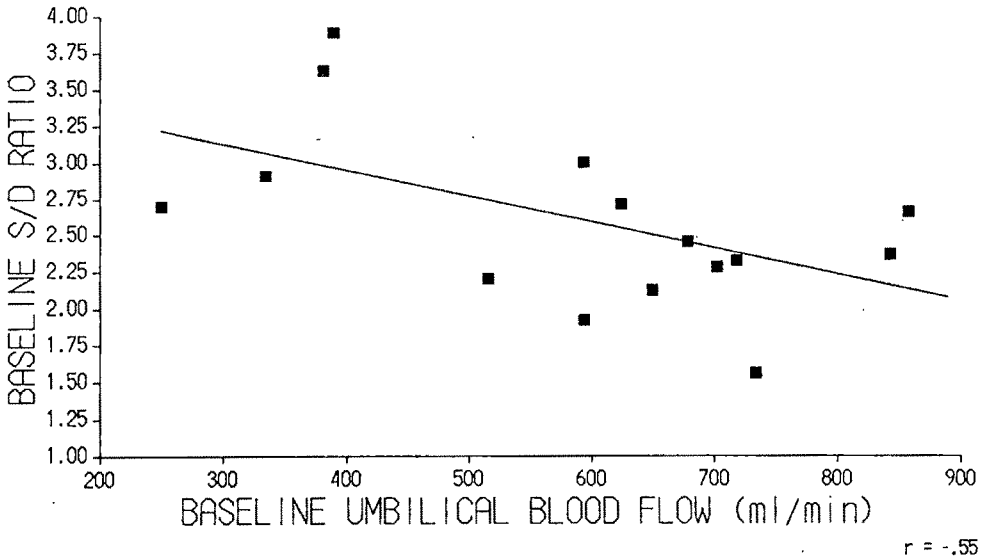

Fig. 3. Relationship between baseline S/D ratio and baseline umbilical blood flow before infusion of vasoactive substances. S/D ratio was significantly related to umbilical blood flow ($r = -0.55$, $n = 15$, $p < 0.05$). Line is least squares fit of data.

($r = -0.68, -0.67$, and -0.71, respectively, $p < 0.05$), and heart rate increased as vascular resistance increased during infusion of norepinephrine ($p < 0.05$) and serotonin ($0.05 < p < 0.1$), ($r = 0.72$ and 0.47, respectively).

Comment

In the present investigation we sought to determine whether the magnitude of a standard velocity waveform index (S/D ratio) is related to fetal umbilical vascular resistance by directly measuring umbilical blood flow and arterial pressure in the chronically instrumented ovine fetus while increasing umbilical vascular resistance by infusion of vasoactive substances. The present study allows accurate measurement of fetoplacental blood flow and umbilical vascular resistance at the same time that blood flow waveforms are obtained. Previously, we performed waveform analysis on umbilical blood flow recordings obtained from implanted transit-time Doppler flow probes and showed that progressive increases in umbilical blood flow during gestation are accompanied by decreasing S/D ratios.[1] We also showed that the waveforms that we record from sheep convey essentially the same information as waveforms obtained externally from human beings. In our previous investigation we computed three different waveform indexes (S/D ratio, resistance index, and pulsatility index).[1] We found that all three indexes correlate very highly with each other ($r = 0.90$ to 0.98). This correlation has been reported previously for externally measured velocity waveforms of human beings.[9] Therefore, in this study we computed only S/D ratio.

The decrease in S/D ratio with gestation is often attributed to progressively greater vascularization and diminishing vascular resistance in the fetoplacental circulation.[2] Support for this hypothesis comes from pathologic correlations. Giles et al.[3] reported that abnormal waveforms occur in association with sclerosis and obliteration of tertiary villus arterioles, and McCowan et al.[4] found a significant negative correlation ($r = -0.71$) between waveform index and the number of small arterioles observed in the fetoplacental circulation. It is not clear at present whether changes in umbilical vascular resistance directly cause changes in the waveform or if a factor common to both, such as increasing vascularization during gestation, causes the decreases in both umbilical vascular resistance and S/D ratio. Morrow et al.[5] were able to dramatically increase S/D ratio in sheep fetuses by embolization with polyethylene microspheres injected into the lower aorta every 30 minutes. Over this short period of time umbilical vascular resistance and S/D ratio were highly correlated. On the other hand, Trudinger et al.[6] observed that a significant change in S/D ratio occurred after only 4 days of daily embolization of the umbilical vascular bed, whereas a change in its vascular resistance was not observable until 9 days of embolization. Therefore, at this time the relationship between S/D ratio and umbilical vascular resistance is not clear. For this reason we have infused vasoactive agents into the fetal hind limb vein while measuring fetal arterial pressure and umbilical blood flow to determine whether the relationship between S/D ratio and umbilical vascular resistance is maintained during acute increases in umbilical vascular resistance.

In the present investigation acute increases in um-

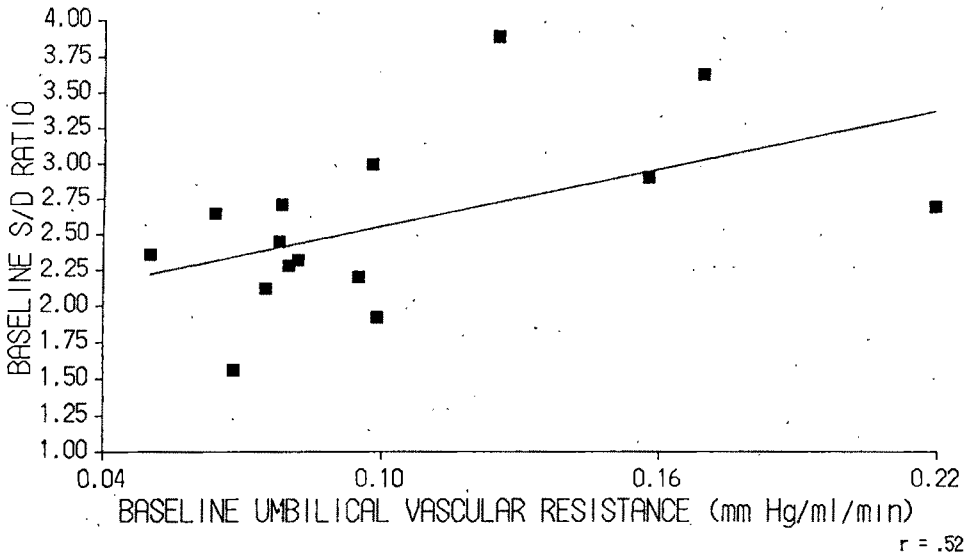

Fig. 4. Relationship between baseline S/D ratio and baseline umbilical vascular resistance before infusion of vasoactive substances. S/D ratio was significantly related to umbilical vascular resistance ($r = 0.52$, $n = 15$, $p < 0.05$). Line is least squares fit of data.

bilical vascular resistance were not accompanied by the predicted change in S/D ratio. All five vasoactive agents produced significant dose-related increases in umbilical vascular resistance, but did not significantly increase the magnitude of the S/D ratio. On the contrary, S/D ratio decreased during infusion of angiotensin II, arginine vasopressin, norepinephrine, and serotonin. Although S/D ratio was significantly related to umbilical vascular resistance before infusion of vasoactive substances, this relationship was not maintained, for the most part, during infusion of these substances, and in the case of norepinephrine, the opposite result occurred; an increase in umbilical vascular resistance was accompanied by a decrease in S/D ratio. The relationship between S/D ratio and umbilical vascular resistance was only maintained during infusion of the thromboxane A_2 sympathomimetic agent U-46619. As umbilical vascular resistance increased during infusion of U-46619, S/D ratio increased.

The reason for the different S/D ratio responses to the different vasoactive agents cannot be determined from this investigation. One possible explanation is that these agents act on different segments of the fetoplacental vascular bed. S/D ratio is related to the number of small arterioles available for blood flow in the fetoplacental vascular bed.[3, 4] In response to the decrease in fetoplacental blood flow caused by infusion of vasoconstrictors smaller arterioles downstream of constricted arterial vessels may dilate. This vasodilation could then result in sufficient microvascular pressure to maintain flow of blood through microvessels or perhaps initiate flow in microvessels that did not have flow previously, thereby maintaining or decreasing S/D ratio despite a decrease in total umbilical blood flow. The thromboxane A_2 sympathomimetic agent U-46619 may produce a more widespread vasoconstriction throughout the fetoplacental vascular bed, resulting in more vessels without flow and an increased S/D ratio.

Other factors that may influence S/D ratio include changes in cardiac output and heart rate. Infusion of these vasoactive substances are likely to alter fetal cardiac output and may thereby alter S/D ratio. However, the effects of each vasoactive substance on cardiac output and S/D ratio are difficult to predict. The effect of heart rate is more straightforward. It has been shown previously[10, 11] and again in this investigation that heart rate and S/D ratio are inversely related. As heart rate decreases there is more time for diastolic flow to decrease, resulting in an increased S/D ratio. Conversely, S/D ratio decreases with increasing heart rate.

In the present investigation, changes in heart rate alone cannot explain the changes observed in S/D ratio during infusion of vasoactive substances. During infusion of angiotensin II and arginine vasopressin, no relationships between S/D ratio and either heart rate or umbilical vascular resistance could be shown. Because heart rate decreased and umbilical vascular resistance increased, an increase in S/D ratio would be predicted during infusion of angiotensin II or arginine vasopressin. Instead, S/D ratio decreased with increasing doses of these two agents. During infusion of norepinephrine and serotonin umbilical vascular resistance and heart rate both increased. The relationships between S/D ratio and heart rate and between S/D ratio and umbilical vascular resistance were of borderline statistical significance during norepinephrine infusion.

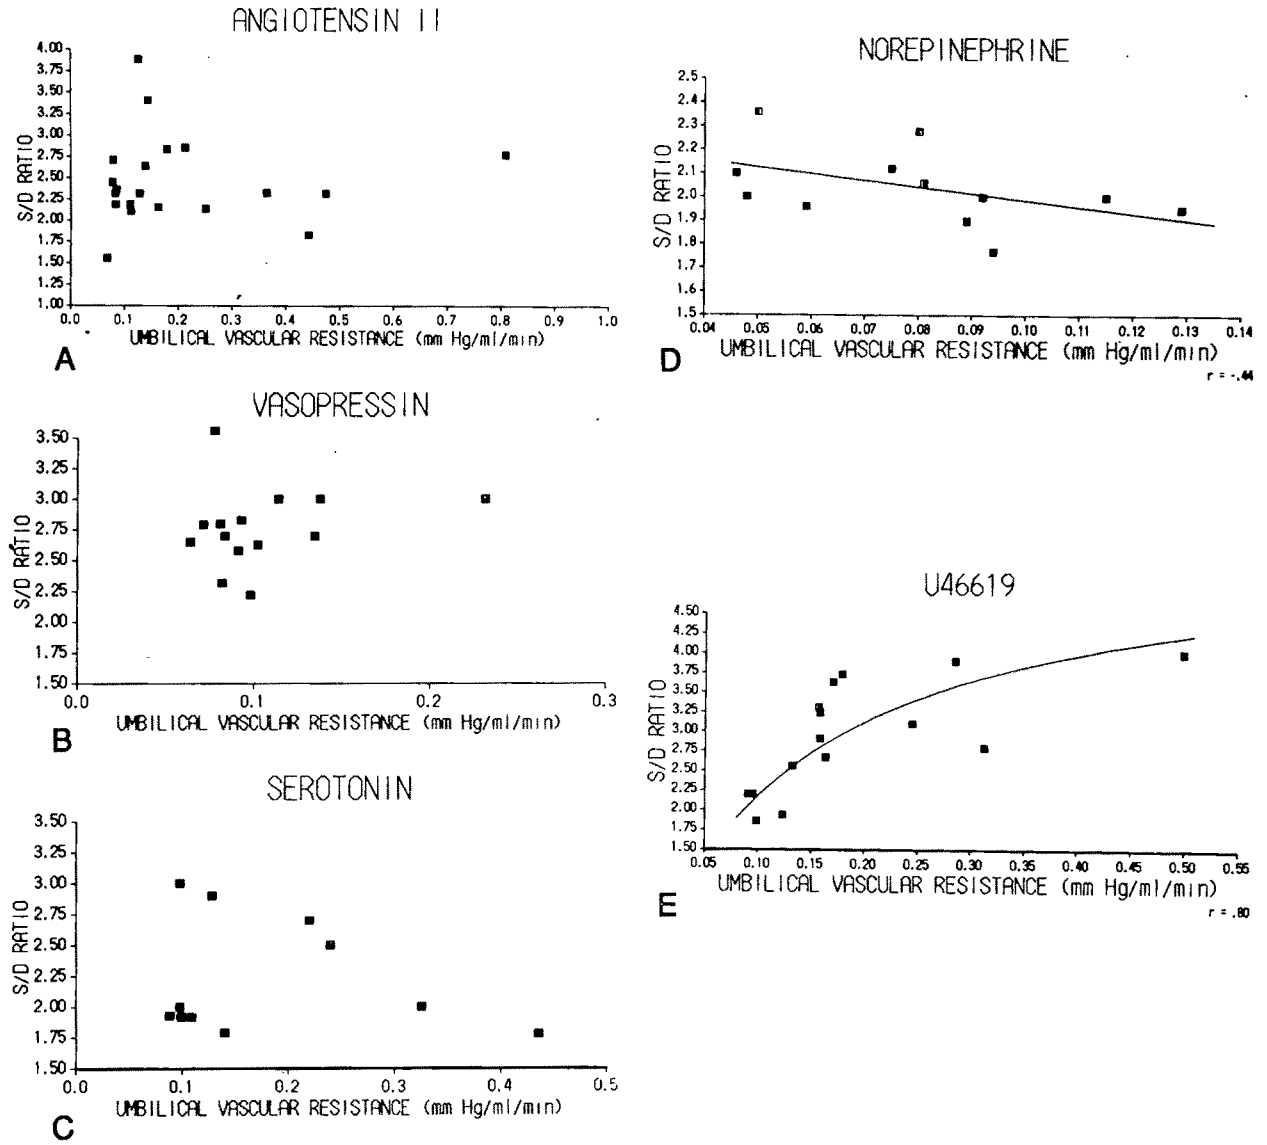

Fig. 5. Relationships between S/D ratio and umbilical vascular resistance during infusion of each of five pressors. **A,** angiotensin II (n = 4 sheep · 4 doses + baseline). **B,** arginine vasopressin (n = 2 sheep · 6 doses + baseline). **C,** serotonin (n = 3 sheep · 3 doses + baseline). **D,** norepinephrine (n = 3 sheep · 3 doses + baseline). Line is least squares fit. **E,** U46619 (n = 3 sheep · 4 doses + baseline). Line is least squares curvilinear fit of S/D ratio^{-1} versus vascular resistance^{-1}. Only the increase in S/D ratio with increasing umbilical vascular resistance during infusion of U-46619 reached statistical significance ($p < 0.01$). S/D ratio appeared to decrease with increasing umbilical vascular resistance during infusion of norepinephrine ($p < 0.10$).

S/D ratio decreased with increasing heart rate as predicted, but decreased with increasing umbilical vascular resistance during norepinephrine infusion. No significant relationships between S/D ratio and either heart rate or umbilical vascular resistance could be observed during serotonin infusion, although S/D ratio decreased with increasing doses of serotonin. In an effort to differentiate between heart rate effects and umbilical vascular resistance effects on S/D ratio, data were analyzed with the use of multiple linear regression. No additive effects of heart rate and umbilical vascular resistance could be shown. S/D ratio changed in the direction expected if umbilical vascular resistance determines S/D ratio only during infusion of U-46619, although the increase in S/D ratio might also be a result of decreasing heart rate with increasing dose of U-46619.

These results support our previous conclusion[1] that the clinical usefulness of waveform analysis may lie more in its ability to detect abnormalities in the size or

function of the fetoplacental vascular bed, rather than strictly changes in umbilical blood flow. Although the magnitude of S/D ratio is related to umbilical vascular resistance under normal conditions, this relationship can disappear during acute changes in umbilical vascular resistance. Under these conditions, S/D ratio is no longer an adequate predictor of umbilical blood flow.

We thank Claudia Chalk, Susan Knippenberg, Kenneth Moore, Cheryl Theiss, and Catherine Mack for their technical support.

Role of the endothelium in adrenergic responses of mesenteric artery rings of pregnant rats

Angèle Parent, BSc, Ernesto L. Schiffrin, MD, PhD, and Jean St-Louis, PhD
Montreal, Quebec, Canada

Responses to adrenergic agents were measured on rings of mesenteric artery of nonpregnant and pregnant rats at 21 days' gestation. In tissues from pregnant rats, norepinephrine, and phenylephrine were less sensitive than in rings from nonpregnant animals; maximum responses were not affected. The effect of isoproterenol was not modified in tissues from pregnant rats. The presence of endothelium in tissue rings was evaluated as fractional relaxation to acetylcholine. Sensitivity to phenylephrine and norepinephrine was inversely related to the effect of acetylcholine. This relationship was similar in slope in both groups but different in intercept. The sensitivity to isoproterenol was directly related to the presence of endothelium (curves similar in both slope and intercept). This demonstrates that the responses of mesenteric artery rings depends on the presence of endothelium. Furthermore, vascular endothelium is not involved in the blunted responses to adrenergic vasoconstrictor during pregnancy. (AM J OBSTET GYNECOL 1990;163:229-34.)

Blood pressure decreases in pregnant rats approaching parturition.[1,2] At the same time the vasculature becomes less sensitive to vasoconstrictor agents such as angiotensin II, arginine-vasopressin, and norepinephrine.[1,3-5] Similarly, the in vitro response to vasoconstrictors is also decreased in isolated vascular tissues from different vascular beds.[6-9]

To explain these phenomena, several studies exam-

ined the role of vasodilating prostaglandins in the regulation of blood pressure and vascular reactivity during pregnancy.[10-12] Indeed, pregnancy was found to be associated with increased uterine release, plasma levels, and urinary excretion of prostaglandins in rats and rabbits.[13-15] The endothelium of blood vessels releases significant quantities of prostaglandins and of endothelium-derived relaxing factor, recently identified as nitric oxide.[16-18] The responses to many vasoconstrictor agents are blunted in the presence of endothelium in isolated vascular tissues.[19-23]

To verify whether the blunted responses to vasoconstrictors in term pregnancy are related to the presence of endothelium, we measured the reactivity of the superior mesenteric artery to vasoconstrictor and vasodilator adrenergic agents. The fractional relaxation of phenylephrine-precontracted vessels by acetylcholine was also measured to ascertain the functional status of endothelium. Although the effects of pregnancy or of vascular endothelium on the responsiveness of blood vessels have been well documented for vasoconstrictor agents, their effects on the action of vasodilator agents have not been studied. Furthermore, the concurrent effects of both pregnancy and the presence of vascular endothelium on the responsiveness of vessels to vasoactive agents have never been studied. These are the subjects of this article.

Methods

Ten-week-old female Sprague-Dawley rats obtained from Charles River Canada (St-Constant, Quebec, Canada) were mated with males of the same age. The morning on which vaginal smears were found to contain spermatozoa was labeled day 1 of gestation. The experiments were performed on the twenty-first day of pregnancy (i.e., when the animals reached 13 to 14 weeks of age); unmated age-matched females served as controls. Rats were decapitated, and the superior mesenteric artery was rapidly removed and placed in cold Krebs solution. The artery was cut transversely to obtain two rings 5 mm long. Small hooks made with 30-gauge needles were carefully inserted into the rings to vertically suspend them in 15 ml glass-jacketed organ baths. The tissues were connected to isometric force-displacement transducers (FT-03, Grass Instrument, Quincy, Mass.) connected to a Grass polygraph #7. They were stretched to a passive tension of 1.0 gm, which in preliminary experiments (Parent A, St-Louis J. Unpublished data) was found to be the optimum one for mesenteric rings of both pregnant and nonpregnant rats. The tissues were then equilibrated for 1 hour in Krebs solution while their passive tension was regularly adjusted. The Krebs solution used in these experiments contained the following compounds: sodium chloride, 118 mmol/L; sodium bicarbonate, 25 mmol/L; potassium chloride, 4.7 mmol/L; calcium chloride, 2.5 mmol/L; magnesium sulfate, 1.18 mmol/L; potassium phosphate, 1.18 mmol/L; and dextrose, 5.5 mmol/L. The pH was 7.4 at 37° C, and the solution was bubbled with a mixture of 95% oxygen and 5% carbon dioxide.

After equilibration, phenylephrine (10^{-6} mol/L) was added to the bathing solution to measure tissue reactivity. At the plateau phase of this response to phenylephrine, the functional integrity of the endothelium was assessed by application of acetylcholine (10^{-4} mol/L; in preliminary experiments it was observed that this concentration of acetylcholine produced a maximal relaxation in all tissues tested when precontracted with this high concentration of phenylephrine (10^{-6} mol/L, ≈ concentration producing 50% of the maximum response or EC_{50}). This response was measured as the fractional relaxation of phenylephrine-induced contraction (i.e., relaxation in centimeters divided by the plateau response to phenylephrine in centimeters). Cumulative concentration-response curves to norepinephrine, phenylephrine, and isoproterenol were subsequently evaluated for each tissue. Concentration-response curves were measured in this sequence in all experiments. The concentration-response curve of isoproterenol was measured after the tissue had been precontracted with 3×10^{-7} mol/L phenylephrine.

Data analysis. Each experimental concentration-response curve was analyzed by microcomputer with the ALLFIT program[24] to determine the concentration producing 50% of the maximum response (EC_{50}) and the maximum asymptote of the response. Statistical comparisons were made by Student's *t* test on the mean pD_2 values (negative logarithm of EC_{50}) and mean asymptote of the individually fitted curves. Linear regression was used to measure the relationship between sensitivity of the agent (pD_2) and the functional integrity of the endothelium (fractional response to acetylcholine). Statistical differences for slope and intercept were evaluated by covariance analysis.

Agents used. The agents used in these studies, (−)-arterenol hydrochloride (norepinephrine), (−)-phenylephrine hydrochloride (phenylephrine), (±)-isoproterenol hydrochloride (isoproterenol), and acetylcholine chloride (acetylcholine) were purchased from Sigma Chemical Co. (St. Louis).

Results

The contractile response to 10^{-6} mol/L phenylephrine was similar in the two groups of mesenteric artery rings obtained from nonpregnant and pregnant rats (0.65 ± 0.09 and 0.64 ± 0.06 gm, respectively; $n = 18$ in each group). The relaxation induced by 10^{-4} mol/L acetylcholine at the plateau response to phenylephrine varied from zero to full relaxation; the mean fractional

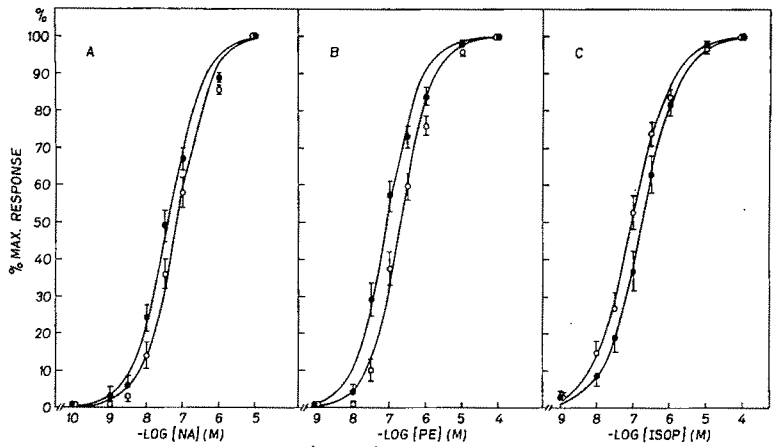

Fig. 1. Concentration-response curves to norepinephrine *(NA)*, phenylephrine *(PE)*, and isoproterenol *(ISOP)* on superior mesenteric artery rings of nonpregnant *(closed circles)* and term pregnant *(open circles)* rats. The contractile responses to norepinephrine and phenylephrine (panels **A** and **B**) are expressed in percent maximum response recorded as tension in grams. In panel *C* the vasorelaxant response to isoproterenol was measured on tissues precontracted with PE/3 × 10^{-7} mol/L) and tissue relaxation is also expressed as percent maximum response. (*Abscissa*, Negative log of agonist concentration in moles per liter. $N = 18$ for each curve.)

	$p = 0.05$	NS	$p < 0.005$	NS	$0.05 < p < 0.10$	NS

relaxation of rings from nonpregnant and pregnant animals was 0.36 ± 0.08 and 0.39 ± 0.09, respectively.

Fig. 1 depicts the concentration-response curves of norepinephrine, phenylephrine, and isoproterenol in mesenteric artery rings of nonpregnant and pregnant rats. Gestation shifted the concentration-response curves of norepinephrine and phenylephrine to the right, indicating a reduction in sensitivity to both agents. In fact, Table I shows that the EC_{50} to both agents doubled in pregnancy, whereas the maximum responses were not affected. The vasorelaxant concentration-response curve of isoproterenol on phenylephrine-precontracted mesenteric artery rings was shifted to the left in tissues from pregnant rats (Fig. 1, *C*), suggesting an increase in sensitivity. This was not confirmed by statistical analysis of the data in Table I, where the enhanced sensitivity to isoproterenol is at the limit of significance, whereas the maximum response is statistically identical in both groups of rings. It should be noted that the responses to 3 × 10^{-7} mol/L phenylephrine to precontract the vessels to obtain concentration-response curve to isoproterenol were statistically similar (0.80 ± 0.07 and 0.72 ± 0.09 gm for tissues from nonpregnant and pregnant rats, respectively).

When the raw data were carefully studied, it was observed that the fractional relaxation induced by acetylcholine had some kind of relationship with sensitivity of these vasoactive agents; hence we performed analysis of covariance on regression lines of the pD_2 for each vasoactive agent with fractional relaxation by acetylcholine as an indicator of the functional presence of the endothelium on the luminal surface of the vessels. The results of this analysis are reported inFig. 2 and Table II. For the three agents, especially for norepinephrine and phenylephrine, it can be seen that the relationship between pD_2 and the fractional response to acetylcholine was highly significant (correlation coefficient Table II) in both control and pregnant rats. When the curves are analyzed with covariance analysis

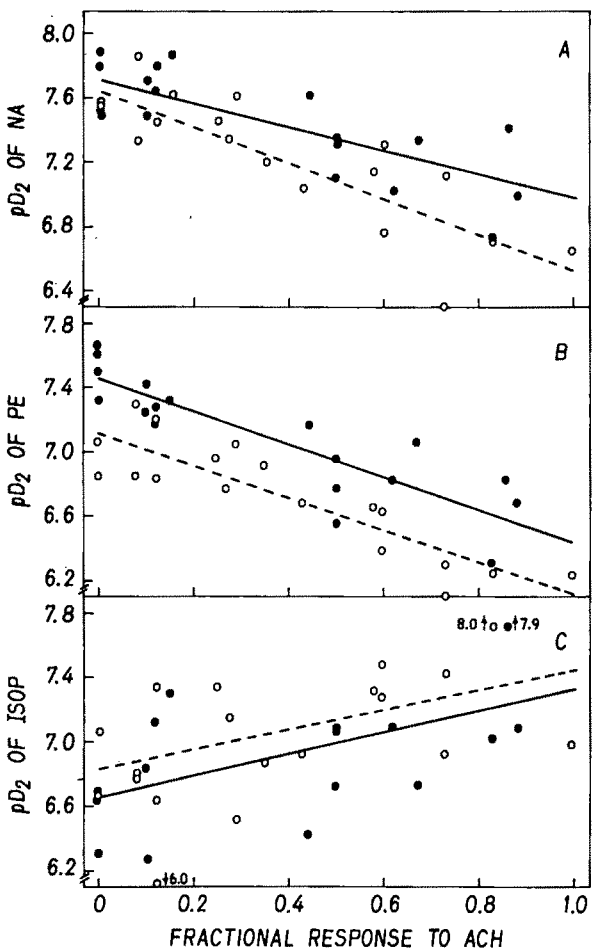

Fig. 2. Linear regression of the sensitivity of superior mesenteric artery rings to norepinephrine *(NA)*, phenylephrine *(PE)*, and isoproterenol *(ISOP)* versus the fractional response of the vessels to acetylcholine (10^{-4} mol/L). Tissues were the same as used in Fig. 1 and were obtained from nonpregnant *(closed circles–solid line)* and term pregnant *(open circles–broken line)* rats. *(Ordinate,* Sensitivity to the agonist as measured by the pD_2 in each tissue. *Abscissa,* Fractional response to acetylcholine [10^{-4} mol/L] on phenylephrine [10^{-6} mol/L]–precontracted vessels.)

(Table II), it is evident that with the three agents the slope of the curves was not different between tissues from pregnant and nonpregnant rats, whereas their elevation was significantly different for the vasoconstrictors but not for isoproterenol. These data, especially the slope, indicate that sensitivity to the vasoconstrictors (norepinephrine and phenylephrine) was decreased by one unit of pD_2 when comparing tissues in which the endothelium was functionally absent with those in which it was functionally intact. For isoproterenol, the increase in sensitivity of pregnant rats was not significant (Fig. 1) nor was the elevation of the curve of the effect of the presence of endothelium on pD_2 (Fig. 2, *C*). This indicates that the measured sensitivity to vasoconstrictor agents, like norepinephrine and phenylephrine, and to vasodilators, like isoproterenol, depends on the functional presence of the endothelium and that this phenomenon is identical for control and pregnant rats. The data also suggest that the decreased sensitivity to vasoconstrictor agents in pregnant rats is independent of the presence of the endothelium.

Comment

The endothelium of blood vessels has numerous important functions, including the induced secretion of substances that affect blood fluidity (e.g., prostaglandins) and vascular tonus (e.g., endothelium-derived relaxing factor).[18] During pregnancy circulating blood decreases in osmolality[25] and vascular resistance is reduced.[26] Because pregnancy is associated with diminished vascular sensitivity to vasoconstrictor agents, we conducted these experiments to evaluate the possible involvement of the endothelium of blood vessels in this lower vascular resistance.

We observed that the sensitivity of the superior mesenteric artery to the three vasoactive agents used (norepinephrine, phenylephrine, and isoproterenol) was dependent on the functional presence of the endothelium in tissue rings. Indeed, sensitivity to both norepinephrine and phenylephrine was decreased tenfold (1 log unit as shown by the slope of the curves in Table II) when the endothelium was functionally intact (total reversal of 10^{-6} mol/L phenylephrine precontraction by 10^{-4} mol/L acetylcholine). It should be noted that the maximum responses to both phenylephrine and norepinephrine were not affected by the functional presence of the endothelium. The increased sensitivity to the vasorelaxant effect of isoproterenol was less markedly influenced by the presence of the endothelium (+0.72 log unit of difference in sensitivity between absent and full responses to acetylcholine). This effect of the endothelium on the sensitivity to vasoactive adrenergic agents was not modified by incubating the tissues in medium containing 10^{-5} mol/L indomethacin (data not shown), indicating that the vasorelaxant influence of the endothelium was not the result of cyclooxygenase activity (e.g., prostaglandin-like).

Decreased sensitivity to vasoconstrictor agents during pregnancy has been observed both in vivo and in vitro.[1, 3, 5, 6, 8, 9] Our results confirm these observations and furthermore show that the presence of the endothelium, although it greatly affects the sensitivity to vasoactive agents, is not responsible for the decreased response to vasoconstrictors during pregnancy. This would have occurred if the endothelium-dependent relaxation of blood vessels had been facilitated during pregnancy, but our data do not support such a role for the endothelium in the decreased sensitivity to vasoconstrictors in this condition. Such a phenomenon was recently noted in spontaneously diabetic rats with a

functional impairment of endothelial-dependent relaxation of blood vessels.[27] Our current finding is supported by the results in Fig. 2 and Table II. In fact, the identical slopes but different intercepts for the curves shown in Fig. 2 indicate that the sensitivity (slope) of endothelium-derived relaxing factor liberation by the endothelium is identical in tissues from nonpregnant and pregnant rats but that the intrinsic sensitivity of vessels to these agents (intercept) is different in the two sets of tissues. This suggests that the decreased sensitivity of blood vessels to vasoactive agents during pregnancy is linked to their overall reactivity without any involvement of the endothelium. Our study does not, however, discriminate whether the decreased reactivity is the consequence of functional modification of smooth muscle cells or of mechanical properties of the blood vessel wall, as previously suggested.[28, 29] Furthermore, the action of isoproterenol, shown to be increased in the presence of endothelium, is not modified in sensitivity during pregnancy, confirming earlier observations from our laboratory that the effect of vasodepressor agents (atrial natriuretic factor[30]; bradykinin, and sodium nitroprusside[31]) are not affected at the end of gestation in the rat.

The results of our experiments confirm the findings of Teeuw and De Jong[1] that the vasodepressor action of acetylcholine is identical in nonpregnant and term pregnant rats, whereas the responses to vasoconstrictor agents are markedly decreased in the latter. This unmodified vascular action of acetylcholine in pregnancy, reported long before the original observation of Furchgott and Zawadsky[16] on the influence of endothelium on vascular tissues, is confirmed and explained in our studies. Indeed, the mean response to acetylcholine (10^{-4} mol/L) on phenylephrine (10^{-6} mol/L–precontracted vessels was identical in tissues of nonpregnant and term pregnant rats (fractional relaxation was 0.36 ± 0.08 and 0.39 ± 0.03, respectively; difference not significant.).

Recently Yanagisawa et al.[32] identified and characterized endothelin, a potent vasoconstrictor peptide from the supernatant of cultured porcine aortic endothelial cells. This peptide, if present in the endothelium of blood vessels of the rat, does not appear to play a role in our results since the changes in sensitivity observed in these experiments with the presence of a functional endothelium were always compatible with the involvement of a relaxing factor.

It was reported that vascular endothelium is actively involved in the metabolism of norepinephrine.[33, 34] This issue was not investigated in our study, but if the results of Fig. 2 are considered, it can be expected that with phenylephrine (panel *B*) and with isoproterenol (panel *C*), this activity, if involved, was not modified during pregnancy. With norepinephrine (panel *A*) there was some change in the slope of regression line linking sensitivity and functionality of the endothelium, but this did not reach statistical significance. If this difference were to occur, the vascular endothelium of pregnant rats would be expected to metabolize norepinephrine more effectively (higher slope); this remains to be investigated.

In conclusion, our series of experiments indicates that sensitivity to vasoactive adrenergic agents is dependent on the presence of the endothelium in the mesenteric artery. This anatomic structure is not responsible, however, for the decrease sensitivity of blood vessels to vasoconstrictor agents at the end of gestation in the rat.

We thank Dr. A. de Lean of our Institute for providing access to his ALLFIT computer program.

HBcAg identification in the placental cytotypes of symptom-free HBsAg-carrier mothers: A study with the immunoperoxidase method

Giovanna Lucifora, MD,[a] Fabio Martines, PhD,[a] Santina Calabro', MD,[a] Giuseppe Carroccio, MD,[a] Amalia Brigandi', MD,[a] and Renato de Pasquale, MD[b]
Messina, Italy

In this study the presence of HBcAg in placental tissue of symptom-free HBsAg-carrier mothers has been determined by the immunoperoxidase technique. The presence of HBcAg in the major placental cytotypes was mostly limited to the trophoblastic lineage. Moreover the activated macrophages with their strong cytoplasmic reaction to the antigen phagocytosis play a remarkable role in the immune response. Because there are continuous channels that link the human amnion through the trophoblastic lineage, including the endovascular trophoblast with maternal decidual vessels, a functional exchange system may be considered valid. This would influence the transmission of infection. (Am J Obstet Gynecol 1990;163: 235-9.)

Key words: HBcAg, immunoperoxidase, trophoblast

During its developing phases the infiltrating trophoblast forms bridges between the tips of the anchoring villi and maternal decidua and invades deep into the lumen of uterine spiral arteries,[1] getting in direct contact with the maternal infected blood. The obstetric anamnesis of HBsAg-carrier mothers, characterized by otherwise unexplained intrauterine deaths, fetal distress, or preterm deliveries, could be explained by placental functional alteration. This has been proved by the histologic evidence acquired when examining specimens. The placentas showed a remarkable congestion in the chorionic villi of the vessels with possible interruption of the walls that communicate with each other. Stroma edema was evident. In this study we have tried to define both the seriousness and the nature of viral

injury in placental tissue of symptom-free HBsAg-carrier methods.

Material and methods

Sections of placentas were obtained from nine women with pregnancies at term; of these, two underwent cesarean section (Table I). All specimens were fixed and embedded in paraffin. The immunoperoxidase technique against HBcAg was carried out with 3,3′-diaminobenzidine and aminoethyl carbazole (Dako Pat kit system, Dako Corp., Santa Barbara, Calif.) on 5 μm sections. Positive and negative controls were also effected. After counterstaining with 0.2% aurum chloride, the sections were mounted in glycerol–phosphate-buffered saline solution.

Results

The HBcAg presence was demonstrated in all placentas of HBsAg-carrier mothers. In the chorionic tissue the endothelia of fetal vessels, fibroblasts, Hofbauer cells, and trophoblastic columns of the septa showed a strong positivity (Fig. 1). The same occurred in the decidua, where the cells of the infiltrating trophoblast, comprising multinuclear cells[2] and large and small cells,[3] were strongly reactive.

The large decidual cells were sometimes surrounded

by a positive border or had a uniform cytoplasmic reactivity. Moreover they often showed a strong nuclear staining (Fig. 2). Clumps of small cells, with very strong reactive cytoplasm, stand out clearly against the negative background of decidual tissue (Fig. 3).

At routine staining by emetoxylin-eosin there appeared a stromal edema and remarkable vasal congestion that sometimes culminates in destruction of fetal-placental blood vessels (Figs. 4 and 5). The congestion appeared related to a probable HBcAg vasculotropic force, because it would act as direct mediator of endothelial cell injury. On the other side the fibrin deposit induced a vascular permeability increase, implicated in the development of tissue edema.[4]

The HBcAg presence was not demonstrated in the endothelium of maternal vessels.

Comment

The condition of HBsAG symptom-free carrier mothers presupposes the activation of immune processes able to confine the viral potentiality within reduced limits, insufficient to cause a manifest illness. At implantation in the uterus the extravillous trophoblasts form anchoring bridges with the maternal tissues, in particular some cells called "endovascular trophoblasts," infiltrate the spiral arteries, and proliferate in vessel lumina.[5] Thus viral injury can operate directly because hepatitis B infection occurs through blood.

Studies carried out with monoclonal antibodies show exactly where trophoblasts are distributed in the placental tissues and the extravillous sites, thus allowing one to distinguish the large, small, and multinuclear trophoblastic cells from those of maternal origin.[2, 3]

If we compare these data with our results it becomes evident that the whole trohpoblastic lineage reacts electively against HBcAg, because it is easily recognized by the strong reactivity assumed by the cytotrophoblastic columns.

The immunoperoxidase staining of the Hofbauer cells and fibroblasts reveals that macrophages are involved as well. Even the small decidual cells, closely associated with lymphocytes in the suppression of the maternal immune response to implantation, are reactive to HBcAg. Moreover, because of their morphologic and histochemical features, they appear as macrophage-like cells. This could suggest that they are Hofbauer cells migrating from the chorionic villi.[3]

In one case of acute hepatitis B the mother was seropositive for HBsAg in the seventh and eighth months but negative in the ninth month, and the baby was born seropositive. This leads us to believe that the last trimester is the most likely time for transplacental spread.[6] Taking into account that recent studies have shown the existence of a selective mechanism of transfer between the amniotic and maternal compartments, we may conclude that placentas play a primary role in transferring the maternal infection to the fetus. However, the viral injury can be very weak and not result in a neonatal disease, especially if the virosis is not aggressive and specific maternal immunoglobulins are present, thus influencing the course of the infection.

Maternal serum α-fetoprotein level useful screening test

To the Editors: The question of Dr. J. D. Stephens (Unexplained elevated maternal serum α-fetoprotein level associated with third-trimester problems [Letter]. AM J OBSTET GYNECOL 1989;161:500) was addressed by different investigators several years ago.

In the more recent study of Walters et al.[1] unexplained elevated maternal serum α-fetoprotein was found to be associated with a higher incidence of previous second-trimester and recurrent abortions as well as preterm delivery, low birth weight, and proteinuric preeclmapsia (both superimposed and de novo), the last complication being first reported by Moore and Redman.[2] Walters et al. found that the incidence of proteinuric preeclampsia was 12.5% in the study group versus 0% in the control group, and accounted for 47% of the babies with low birth weights in the study group. Maternal serum α-fetoprotein level may become the most useful screening test for high-risk pregnancies.

Clindamycin dosage scheduling for acute pelvic infection

To the Editors: Clindamycin phosphate continues to be a widely used antibiotic for the infections of the female genital tract. Recent studies have indicated that administration of clindamycin 600 mg every 8 hours combined with gentamycin or tobramycin is effective in curing presumed infections of intraabdominal origin in 84%[1] to 95%[2] of the patients. *Bacteroides fragilis* is extremely sensitive to clindamycin and minimal inhibitory concentration averages <1.00 μg/ml. The reported minimal inhibitory concentration after the fourth dose of intravenous clindamycin is 1.7 μg/ml[4] and this should provide enough concentration to cover the presumed infections with *Bacteroides fragilis*.

The infectious diseases departments in many institutions recommend that the standard dose of injectable clindamycin need not be higher than 600 mg every 8 hours. Since this policy was adopted at our institution we did a retrospective study to determine whether there was any difference in the clinical response of the patients admitted for pelvic inflammatory disease to clindamycin 900 mg every 8 hours to clindamycin 600 mg every 8 hours. Forty-five patients were selected randomly from each group and their findings are presented in Table I. Both groups of patients received gentamycin or tobramycin.

Table I. Average number of days for response

	White cells	*Temperature*	*Abdominal pain*
Clindamycin 900 mg every 8 hr	3	2.8	3.0
Clindamycin 600 mg every 6 hr	4	2.8	3.2
p Value	—	—	NS

The results indicate that clindamycin 600 mg every 8 hours is equally effective as 900 mg every 8 hours. The regimen of clindamycin 600 mg every 8 hours has resulted in a 30% decrease in cost of antibiotics at our institution. It is hoped that with the previous studies and more prospective studies, the Center for Disease Control recommendations will change to 600 mg clindamycin every 8 hours for presumed pelvic inflammatory disease.

Magnesium supplementation in pregnancy

To the Editors: It was with great interest that we read the paper of Sibai et al. (Sibai BM, Villar MA, Bray B. Magnesium supplementation during pregnancy: a double-blind randomized controlled clinical trial. AM J OBSTET GYNECOL 1989;161:115-9).

In view of the difference in results between this study and our own[1] it is regrettable that the authors have not adequately outlined some major differences in study design:

Table I. Differences in the results of the Sibai study becoming significant with a 10-fold increased population

	p Value
Birth weight	<0.005
Placental weight	<0.002
Small for dates	<0.05
Apgar score at 5 min < 7	<0.05

1. The study of Sibai et al. compares a low-dose versus a high-dose magnesium supplementation, whereas in our study no magnesium supplementation was compared with a high dose.
2. The study group of Sibai et al. was restricted to young primigravid women to have patients at higher risk of preeclampsia.
3. Furthermore, magnesium supplementation was started at a later state in pregnancy, 17.8 in average versus 13.3 weeks in our study.

If the authors find an extrapolation to a study population 10 times the one used acceptable to rule out statistical significance in the difference of frequency of preterm labor in the two groups, they should have applied the same approach to other parameters and would have found significant differences in favor of the high magnesium group (Table I).

It should be clearly stated that Sibai et al. did not find an effect of elevation of magnesium supplementation from 100 mg to 465 mg daily with intake started after 13 weeks' gestation in young primiparas in the prevention of the development of preeclampsia.

They certainly have not disproved our finding of beneficial effect on overall outcome of early onset high-dose magnesium supplementation in an unselected group when compared with no magnesium supplementation.

Reply

To the Editors: I would like to thank Drs. Spätling and Fallenstein for their interest in our study and for giving me the opportunity to outline some of the problems in their study.[1] It is important to note that we used the same dose of the study drug and the same placebo prepared by the same company that prepared their drugs. In addition, we made sure that all patients received the same prenatal vitamins to ensure similar intake of additional magnesium by both groups. Moreover, we performed serial nutritional recall to assess the amount of magnesium intake from food in both groups. Both of these points are very basic for any nutritional supplementation study. Unfortunately, the above authors did not include these in their study design. I assume that pregnant women in Europe receive prenatal vitamins and that their diet contains some magnesium. Thus, the conclusions of the study by Spätling and Spätling are inappropriate since they did not know the amount of magnesium intake in each group.

Our study included a homogenous group of patients after excluding all associated medical and obstetric complications. Thus, any differences in outcome will definitely be attributed to magnesium effect. In contrast, their study included a heterogenous group of patients with various obstetric complications. As a result, the difference in outcome between the two groups were because of differences in patients studied rather than because of magnesium. It is obvious that all the differences were a result of a higher number of patients with either bleeding or incompetent cervix in the placebo group. I do not believe that magnesium is such a magic drug with the ability to prevent the above complications.

A difference of an average of 4 week's gestation at the time of enrollment between the two studies is meaningless because most women received an average of 22 weeks of magnesium supplementation. In addition, most pregnant women will start prenatal care around this time period.

Finally, I agree with the recent comments of Hibbard that the evidence for dietary supplementation of magnesium in pregnancy is unconvincing.

Secretion of phospholipases by bacterial pathogens may initiate preterm labor

To the Editors: Evidence for the role of infection in the cause of preterm labor continues to accumulate[1]; however, cause and effect remain to be established. Normal labor at term is associated with an increase in the synthesis of prostaglandins within the uterus.[2] Recently Lopez-Bernal et al.[3] compared prostaglandin E_2 (PGE_2) production by fetal membranes and placenta after preterm labor with that after term labor. The production by amnion and chorion decidua was highest after labor at term, with the lowest rates of production seen after uncomplicated preterm labor. However, amnion and chorion decidua obtained after preterm labor associated with chorioamnionitis produced high levels of PGE_2. The authors concluded that chorioamnionitis causes preterm labor by increasing prostaglandin production in the fetal membranes.

We have previously published in the JOURNAL[4] our finding that common vaginal pathogens release a substance that increases arachidonic acid metabolism when

Table I. Phospholipase A_2 activity in bacterial-conditioned media and ability to stimulate amnion cell arachidonic acid metabolism

Organism	*Phospholipase$_2$ activity (nmol fatty acid hydrolyzed/hr) (mean ± SD)*	*Increase in amnion arachidonic acid metabolism (% of control)*
Streptococcus viridans	11.5 (2.1)	283
Group B streptococcus	10.2 (1.7)	269
Bacteriodes fragilis	6.6 (1.8)	236
Escherichia coli	5.6 (1.9)	202
Lactobacillus acidophilus	0.6 (0.4)	97

added to amnion cells. Both lipoxygenase metabolism to hydroxyeicosatetraenoic acids and cyclooxygenase metabolism to PGE_2 are increased by addition of this substance but the increase in metabolism to PGE_2 predominates. These changes are very similar to those seen in amnion cells obtained after spontaneous labor at term, compared with those obtained at elective cesarean section before labor. We postulated that bacteria may mediate these effects by release of phospholipases.

We have since found that addition of purified phospholipase A_2 to amnion cells results in changes in arachidonic metabolism identical to those caused by addition of bacterial products. We also measured phospholipase activity in the bacterial-conditioned media used in our original experiments with the methods described by Bonney et al.[5] The data shown in Table I revealed that there was a strong positive correlation between the phospholipase activity in any individual bacterial-conditioned medium and the ability of that medium to stimulate overall arachidonic acid metabolism in amnion cell cultures ($r = 0.92$).

Although not definitive proof of cause and effect, the correlation between phospholipase release and stimulation of arachidonic acid metabolism and the similarity between the effects of bacterial products and purified phospholipase A_2 support the hypothesis that common bacterial pathogens release phospholipase, which stimulates prostaglandin production within the fetal membranes. This then may be one mechanism by which preterm labor is initiated.

Zinc, preeclampsia, and γ-aminobutyric acid

To the Editors: An oversight has occurred in an article of Dr. Lazebnik et al. (Lazebnik N, Kuhnert BR, Kuhnert PM. Zinc, cadmium, and hypertension in parturient women. Am J Obstet Gynecol 1989;161:437-40). The authors state that their finding of lowered placental zinc in preeclampsia "has not been previously reported." We did, in fact, report in 1985 low zinc in placentas of preeclamptic patients,[1] perhaps reflective of generally low tissue zinc including that of brain where it might be relevant to eclampsia.

We continue to believe that low zinc might affect concentrations of brain γ-aminobutyric acid, the inhibitor neurotransmitter, and have some new data. Preliminary results are that plasma γ-aminobutyric acid is lower in preeclamptic patients (93 pmol/ml ± 12 SD) than in normal women in labor (132 pmol/ml ± 38 SD) ($p < 0.05$). There is a drop in plasma γ-aminobutyric acid of 15 pmol/ml in normal women early in labor. Normal nonpregnant women have a plasma γ-aminobutyric acid concentration of 127 pmol/ml (± 17 SD) similar to normal women in labor.

Zinc is involved in maintenance of pyridoxal phosphate concentrations by its activation of pyridoxal kinase[2]; pyridoxal phosphate is a decarboxylation cofactor and deficiency lowers brain γ-aminobutyric acid.[3] The decrease in this inhibitory neurotransmitter would lower the seizure threshold. Significant zinc malnutrition might interfere with transcription of deoxyribonucleic acid to ribonucleic acid[4] and thus production of the protein enzyme pyridoxal kinase.[5] Although plasma pyridoxal phosphate has been found to be insignificantly lower in preeclampsia than in normal pregnancy,[6] "plasma pyridoxal phosphate measurements alone may not accurately reflect either vitamin B_6 nutriture or tissue pyridoxal phosphate levels during pregnancy."[7] Low zinc may be related through pyridoxine metabolism to low γ-aminobutyric acid and seizures.

Association between autoantibodies and unexplained infertility unproved

To the Editors: Taylor et al.'s recent article (Taylor PV, Campbell JM, Scott JS. Presence of autoantibodies in women with unexplained infertility. AM J OBSTET GYNECOL 1989;161:377-9) claims to show that there is an increased incidence of antibodies to smooth muscle, nuclear components, and phospholipids in women with unexplained infertility. The authors postulate a pathogenic role for these antibodies. Unfortunately, they use a group of pregnant women as their control, which invalidates their conclusion. Use of a group of women with a variety of known causes for their infertility (anovulation, tubal factor, male factor) would be indicated. Taylor's results could be explained in several ways: pregnant women may have a lower level of autoantibodies; alternatively, infertility itself, whether explained or unexplained, could be associated with a higher level of autoantibodies.

Other features of their article need clarification. They state that their infertile group had a laparoscopy that showed "no intrapelvic bar to pregnancy"; what does this mean? Did they have a totally normal pelvis, or were there abnormalities found that were not considered absolute barriers to pregnancy? Neither hysteroscopies nor hysterosalpingograms were performed; were uterine causes of infertility ruled out? Endometrial curettage showed secretory endometrium; was it in phase or were luteal phase defects ruled out by other means?

The association between autoantibodies, especially antiphospholipids, and recurrent pregnancy losses, has been established.[1] An association with endometriosis has been postulated, but further work is needed in this area.[2] I do not believe that Taylor et al.'s study shows an association between autoantibodies and unexplained infertility.

Reply

To the Editors: In the statement that our infertile group had no intrapelvic bar to pregnancy we meant that laparoscopy showed no evidence of pelvic adhesion nor any sign of endometriosis, with both fallopian tubes being patent to the passage of dye and no evidence of clubbing at the fimbrial end. The endometrial curettage specimens all showed secretory endometrium in phase with the patient's cycle.

Comparison of the group of pregnant women with our group of normal, nonpregnant, age-matched controls (data for the latter not given in the article) shows that a lower level of autoantibodies was not associated with pregnancy per se in our group. Therefore comparison of our infertile group with normal, nonpregnant controls would have confirmed an increased prevalence of autoantibody in these infertile women. However, Dr. Maier's point concerning the control group with explained infertility is entirely valid and emphasizes the need for further work in this area.

Modified laparoscopy for monitoring transcervical surgery

To the Editors: Use of laparoscopy during transcervical resection of the uterine septum, intrauterine adhesion, and submucous myoma under hysteroscopic control has been reported.[1] To prevent accidental trauma such as uterine perforation or further subsequent intestinal trauma, a laparoscopy was simultaneously used to monitor the transcervical hysteroscopic operation. The procedure was to darken or to turn off the light from the laparoscope while monitoring the light transilluminated from the hysteroscope. If the light from the hysteroscope can be clearly visualized from the laparoscope, it is a dangerous sign that the tip of the hysteroscope is closely approaching the uterine surface. However, because the accuracy of this method greatly depends on the experience of the laparoscopist, even with cautious monitoring, uterine perforation is still encountered. On the other hand, incomplete excision of the intrauterine lesion is experienced because of fear of perforation.

To solve these problems we developed a modified two-step method. The first step involves the conventional monitoring procedures described previously. When the hysteroscope is advanced to a certain point, the second step is performed. The second step is to place the laparoscopic light near the surface of uterus

while darkening or turning off the light from the hysteroscope. By monitoring the light transilluminated from the laparoscope, the operator can not only estimate the thickness of the remaining uterine wall, but also determine the incomplete resected portion.

This modified method enables a homogeneous fundal resection and prevents the risk of uterine perforation and incomplete intrauterine resection.

Combination therapy has potential complications

To the Editors: I read with interest the case reported by Snyder and Cardwell (Snyder SW, Cardwell MS. Neuromuscular blockade with magnesium sulfate and nifedipine. AM J OBSTET GYNECOL 1989;161:35-36). I would like to point out a few inaccuracies mentioned in the article.

First, magnesium sulfate is not a calcium channel blocker but a calcium antagonist.

That the authors are not aware of any reports of serious side effects is because they have limited experience with nifedipine[1] and because the combination of nifedipine and magnesium sulfate is seldom used in practice rather than relatively frequently as they state in their article. The potential severity of the complications in combination therapy is highlighted by the occurrence of neuromuscular junction blockade after a homeopathic dose of 500 mg of intravenous magnesium sulfate.

Finally, the use of β-sympathomimetic agents alone for tocolysis is associated with significant maternal[2] and fetal[3] morbidity. The use of combination therapy for tocolysis should be discouraged.[4, 5]

However, I would like to congratulate the authors for publishing this case of drug interaction, which shows how dangerous can be the concomitant use of smooth muscle relaxing agents with different modes of action.[4, 5, 6]

Reply

To the Editors: We are glad to hear of Dr. Frolich's interest in our recent case report. Perhaps some clarification of the language in the article is needed.

First, calcium antagonists should be used in our report wherever "calcium channel blockers" appears. It may be more accurate to consider magnesium as an ionic antagonist (if it is one at all) and nifedipine as an organic one.[1] We do not pretend that a clear understanding of the mechanism of action of either agent in uterine muscle is known.

The remainder of the comments I think relate to the section of our case report that describes the absence of serious interaction of neuromuscular blockers and calcium antagonists, which are used in combination relatively commonly (as patients with hypertension and angina come to the operating room for anesthetics). We in no way meant to underemphasize the magnitude or gravity of side effects of tocolytics, alone or in combination.

Heterotopic pregnancy associated with assisted reproductive technology

To the Editors: We read with interest Gamberdella and Marrs' article and its discussion (Gamberdella FR, Marrs RP. Heterotopic pregnancy associated with assisted reproductive technology. AM J OBSTET GYNECOL 1989;160:1520-4) on the incidence and management of heterotopic pregnancy associated with assisted reproduction.

The authors quoted the incidence of heterotopic pregnancies in the literature to be between 1/2600 and 1/30,000 pregnancies. Studies from Israel[1] and Belgium[2] gave an incidence of 1/6778 and 1/4112, respectively.

With the advent of in vitro fertilization–embryo transfer techniques, more patients with tubal damage have conceived with a high incidence of ectopic pregnancy (5% as quoted by Cohen et al.[3]). Consequently,

the incidence of heterotopic pregnancy has increased even further.

Nine cases of heterotopic pregnancies occurred after in vitro fertilization–embryo transfer at Hammersmith Hospital, London, between September 1984 and November 1988. The incidence was 9/312 clinical in vitro fertilization pregnancies (2.9%),[4] which to our knowledge is the largest collected series from one unit.

Gamberdella and Marrs reported the inability of the β-human chorionic gonadotropin level on day 23 after egg collection to delineate the heterotopic pregnancy in their case.

In our experience,[4] earlier levels of serum human chorionic gonadotropin (days 12, 14, and 16 after egg collection) may indicate the presence of multiple gestation. The sonographic appearance of only one intrauterine sac on vaginal ultrasonographic examination should further increase the index of suspicion for heterotopic pregnancy.

We believe that the readers should be aware of this high incidence of heterotopic pregnancy because the diagnosis of this potentially fatal condition could be easily missed.

Plasma atrial arginine vasopressin levels vary little between preeclamptic and control patients

To the Editors: The recent article by Hatjis et al. (Hatjis CG, Greelish JP, Kofinas AD, Stroud A, Hashimoto K, Rose JC. Atrial natriuretic factor maternal and fetal concentrations in severe preeclampsia. Am J Obstet Gynecol 1989;161:1015-9) on the plasma concentrations of atrial natriuretic peptide in patients with preeclampsia supports similar observations that we reported in such patients a couple of years ago.[1] In addition to measuring plasma atrial natriuretic peptide concentrations in patients with preeclampsia, we also measured the plasma concentrations of arginine vasopressin.

Contrary to our expectations, which were based on previously published data that indicated a contracted plasma volume in patients with preeclampsia,[2] we found that the plasma arginine vasopressin concentrations in our preeclamptic patients were not significantly different from those of the control population. Therefore the elevated atrial natriuretic peptide levels in preeclamptic patients are most likely because of left atrial distension as a result of systemic hypertension and not because of volume overload in these patients. Similarly, plasma arginine vasopressin levels in our preeclamptic patients with presumed contracted plasma volume were not elevated, also because of the postulated left atrial distension. This left atrial distension would negate any stimulatory effect of the contracted plasma volume status on release of arginine vasopressin in these patients.

It is also unlikely that the elevated plasma atrial natriuretic peptide levels in patients with preeclampsia are significantly due to diminished clearance of the peptide. Atrial natriuretic peptide is cleared not only by the kidneys but also by the liver and skeletal muscles[3] and none of the patients with preeclampsia who we studied showed any significant hepatic or renal function impairment.

Pregnancy loss terminology

*To the Editors:*We support Drs. Pridjian and Moawad (Pridjian G, Moawad AH. Missed abortion: Still appropriate terminology? Am J Obstet Gynecol 1989; 161:261-2) in their recommendation to change the terms used to categorize pregnancy loss. The term *missed abortion* does nothing to define the gestational age or possible cause of pregnancy loss and is no longer used in our clinic. Moreover, the arbitrary designation of "spontaneous abortion" as a pregnancy loss of <20 weeks' gestation is no longer clinically useful. Like the authors, we attempt to define pregnancy loss ultrasonographically as either an anembryonic gestation (blighted ovum) or fetal death (first or second trimester). A precise history of previous pregnancy losses

should also be obtained. It is often helpful to determine whether the patient or her doctor heard the fetal heart rate with a Doppler device or stethoscope. Some patients recall seeing a fetus, indicating that the loss was not an anembryonic gestation. Often, however, (especially with first trimester losses), neither the patient history nor the available records indicate whether a fetus was present. An appropriate term for this type of pregnancy loss is *spontaneous abortion, fetal status unknown.*

Early pregnancy ultrasonography may provide prognostic information. In normal women with uncomplicated pregnancies, the presence of a live fetus in the first trimester predicts a very low rate of subsequent pregnancy loss (<4%).[1] Among otherwise normal women with threatened abortion, the presence of a live fetus by first- or early second–trimester ultrasonogram suggests a subsequent loss rate <15%.[2, 3] But similar prognostic data are not available for women with recurrent pregnancy loss, and the utility of first-trimester ultrasonography in such patients remains undefined. For women with recurrent pregnancy loss, systematically gathered, prospective data are needed to determine how first-trimester ultrasonography might be useful in defining the cause of pregnancy loss and the prognosis in the current pregnancy.

We disagree with Drs. Pridjian and Moawad on one point made in their Clinical Opinion article. They recommended that the physician should "promptly" schedule dilatation and curettage if "nonviability of a pregnancy is ascertained." According to the scheme they outlined, "nonviability" would be diagnosed when "at ≥7.5 weeks there is no fetus." One should be cautious about immediate evacuation of the uterus with an empty gestational sac ≤8 weeks' size. In our experience this would occasionally have led to the termination of a normal pregnancy. In some cases it may be better to repeat the ultrasonographic evaluation 5 to 7 days later to exclude inaccurate measurements and to confirm that the gestation is truly anembryonic.

D. Ware Branch, MD, and James R. Scott, MD

Department of Obstetrics and Gynecology, University of Utah School of Medicine, Salt Lake City, UT 48132

Reply

To the Editors: We appreciate the comments of Drs. Branch and Scott, who are in general agreement with our proposed change in terminology.

We share their concern that one should be cautious in immediate evacuation of the uterus with an empty gestational sac ≤8 weeks' size. However, the ability to see the fetal pole in a normal pregnancy at 7½ weeks gestation is equipment dependent. In our institution the lack of a fetal pole at ≥7½ weeks' gestation is diagnostic of an anembryonic, abnormal gestation. Timor-Tritsch et al.[1] stated that with the use of a 6.5 MHz transvaginal mechanical sector scanner, at 6½ weeks (one week earlier to our proposed 7½ weeks), not only should a fetal pole be seen, but a heartbeat must be seen.[1] Clinicians should be familiar with the ultrasonographic capabilities in their respective institutions and practice accordingly. Patients with insulin-dependent diabetes may require repeat scanning because investigators suggest their fetuses may show a growth delay.[2]

Undoubtedly, if there is any concern with accuracy or capabilities of ultrasonographic diagnosis, unsure dates, or potential growth delay, the prudent course of action, as noted in the footnote in our scheme, would be to repeat the scan.

Sapphire probes in obstetric laser surgery

To the Editors: In their brief report on death caused by embolism with hysteroscopic intrauterine surgery performed with a neodymium: yttrium-aluminum-garnet (Nd:YAG) laser (Baggish MS, Daniell JF. Death caused by air embolism associated with neodymium:yttrium-aluminum-garnet laser surgery and artificial sapphire tips. Am J Obstet Gynecol 1989;161:877-8) the authors concluded that "use of sapphire tips for intrauterine laser surgery is associated with grave hazards for the patient." Unfortunately, this conclusion is unwarranted. First, in both cases room air was used as a coolant for the distal probe. Use of room air is contraindicated for any hysteroscopic procedure because of the danger of gas embolism compared with use of carbon dioxide, which is much more soluble in blood. Even so, the flow rate of carbon dioxide used to cool the sapphire probes can easily be in excess of 1 L/min, clearly not a safe level of flow within the uterus, the vascular tree of which can quickly absorb enough carbon dioxide to cause systemic acidosis, leading to cardiac arrhythmia even if the solubility of carbon dioxide in blood is not exceeded.

There is a legitimate role for use of the sapphire tips in intrauterine operations, including incision of the uterine septum and submucous myomectomy. Because of the small volume of the uterus and production of some smoke, this cannot conveniently be done with carbon dioxide distention of the uterus. Therefore it must be performed with some liquid medium as a distending source. Under those circumstances, the tip may be cooled with a liquid because gas causes bubbles to form in the distending medium. There is no reason to use the sapphire probe for endometrial ablation where the scatter effect of the bare fiber is desired. The fiber needs no cooling flow.

To indict the sapphire tip in intrauterine operations is to focus on the most obvious suspect, but misses the actual mechanism by which the untoward effect is generated.

Reply

To the Editors: We appreciate Dr. Corson's interest in our communication in brief in which we reported two deaths related to the use of artificial sapphire tips. Both deaths were associated with intrauterine operation performed with the Nd:YAG laser via coaxial fiber-sapphire probes (tips). Unfortunately, space limitations prevented us from relating the details of the grievous injuries inflicted on other patients by the use of these devices. The full scope of these catastrophies has been reported subsequently.[1] Recently, even another death occurred with the use of sapphire tips in a general surgery procedure. The magnitude of these tragic outcomes is particularly odious when viewed in the context of the admirable safety record associated with the general applications of lasers in gynecology. Contrast the lopsided volume of cases safely performed with carbon dioxide, argon, KTP 532, and bare fiber–delivered Nd:YAG lasers with the minuscule number performed with Nd:YAG laser–ensembled sapphire tips. This disparity is more blatant when coupled with the appalling number of mortalities associated with the latter technology.

Clearly any gas, including carbon dioxide, should be used with trepidation for cooling sapphire tips. Curiously, within the past month a widely read publication described the option of gas cooling at flow rates ranging between 20 and 30 ml/sec, which translates to 1200 to 1800 ml per minute.[2] Because the sapphire tip must make contact with the tissue to effect an action, the coolant gas enfilades the disrupted stromal planes and seeps into vascular spaces. This phenomenon creates circumstances favorable for lethal carbon dioxide gas embolus.

None of our reported cases occurred before 1986, and one case occurred as late as 1988. Nevertheless, even today surgeons and gynecologists continue to use gas to cool the tips. Although these ephemeral devices offer few compelling advantages, we agree that if they must be used, they should always be cooled with water or saline solution. In regard to the examples referred to by Dr. Corson, it is our belief that the Nd:YAG laser delivered by a bare fiber is superior to a sapphire tip both in its simplicity and superior hemostasis for the hysteroscopic treatment of submucous uterine myoma.[3] Uterine septa may be cut hysteroscopically by scissors or alternatively by the Nd:YAG laser with bare, extruded fibers, or with other fiberoptic lasers.[4]

The message we convey is that further animal studies and carefully designed clinical trials are required to detect *every* dangerous aspect of these sapphire devices. Technologic preferences must always take a second berth when questions of patient safety exist.

Epidural analgesia and cesarean section for dystocia

To the Editors: I read with interest the recent report by Thorp et al. (Thorp JA, Parisi VM, Boylan PC, Johnston DA. The effect of continuous epidural analgesia on cesarean section for dystocia in nulliparous women. AM J OBSTET GYNECOL 1989;161:670-5). The authors stated that "there are many mechanisms by which epidural analgesia could increase the incidence of cesarean section for dystocia." Since the authors believe that there are "many mechanisms," it is surprising that they listed only three.

1. The authors suggested that "a decrease in uterine activity without appropriate intervention with oxytocin could result in more cesarean sections for dystocia." This seems irrelevant to their study because all patients were managed "according to the principles of active management of labor."
2. The authors suggested that "relaxation of the pelvic diaphragm could predispose fetuses in a cephalic presentation to minor malpresentations such as occipitoposterior, deflexion, and asynclitism." But the authors did not compare the epidural and nonepidural groups with regard to incidence of abnormal position of the vertex. Even

if the authors had documented an increased incidence of abnormal position in the epidural group, they should have also considered the possibility that the abnormal position preceded (or even prompted) the use of epidural analgesia.

3. The authors stated that "epidural analgesia could decrease the maternal stimulus and ability to push during the second stage." It is not clear whether this potential mechanism is relevant to their study because they did not report the incidence of cesarean section for second-stage dystocia in the two groups. This suggestion is in conflict with the results of two prospective, randomized studies[1,2] in which nulliparous patients receiving epidural analgesia were randomized to receive additional local anesthetic or saline solution–placebo after 8 cm of cervical dilation. Women who continued to receive local anesthetic until delivery were *not* more likely to undergo cesarean section than women who received the placebo.[1,2]

The authors failed to substantiate any mechanism(s) by which epidural analgesia could have increased the incidence of cesarean section in their patient population. The use of multivariate analysis notwithstanding, the major problem with any nonrandomized assessment of the influence of epidural analgesia on the method of delivery is the potential for selection bias. Why do some, but not all, nulliparous women request and receive epidural analgesia during labor? The authors did not acknowledge the possibility that the very reason(s) why some, but not all, parturients request and receive epidural analgesia may relate to a greater likelihood of abnormal labor and increased risk for cesarean section. The authors suggested that "ethical considerations" would preclude the performance of a prospective study in which nulliparous patients are randomized to receive or not receive epidural analgesia during labor. In my judgment, this betrays a lack of conviction. For example, "ethical considerations" have not precluded the performance of studies in which patients were randomized to undergo electronic fetal heart rate monitoring or intermittent auscultation. If use of epidural analgesia increases the incidence of cesarean section for dystocia, it should be confirmed in an appropriate scientific study. But what if the use of epidural analgesia does not increase the incidence of cesarean section? Nonrandomized studies such as theirs may inappropriately discourage obstetricians and patients from use of the most effective method of intrapartum analgesia.

I acknowledge that prospective, randomized studies are difficult and tedious. But results of nonrandomized studies such as this one cloud rather than clarify the issue. I urge the authors and others to perform prospective studies that provide more meaningful information regarding the relationships between epidural analgesia and the method of delivery.

Reply

To the Editors: We appreciate Dr. Chestnut's interest in our research. Indeed, "There *are* many mechanisms by which epidural analgesia could increase the incidence of cesarean section for dystocia."[1] The following potential mechanisms have a basis in the literature: (1) decrease in uterine activity; (2) prolongation of first stage of labor; (3) relaxation of pelvic diaphragm, therefore predisposing to minor malpresentation; (4) decrease in maternal urge to push; (5) decrease in maternal ability to push; (6) prolongation of second stage of labor; (7) increased risk of instrumental vaginal delivery, which is less likely to be pursued for medicolegal reasons.

This investigation was not designed to ascertain the exact mechanisms operative in our study. However, any one or combination of the above mechanism(s) could easily account for the increased incidence of cesarean section associated with epidural in our study.

Dr. Chestnut readily cites his own two randomized prospective studies that suggest that use of epidural anesthesia does not increase the incidence of cesarean section.[2,3] Unfortunately, both the experimental and control groups in these studies[2,3] had epidural anesthesia until 8 cm of cervical dilatation and then were randomized to receive either placebo or a local anesthetic agent through the epidural catheter. Therefore these studies[2,3] did not assess the significant effect of epidural anesthesia before 8 cm of cervical dilatation. In fact, when both studies[2,3] are combined, the majority of cesarean sections (11/19) were excluded because they were performed before 8 cm of cervical dilatation. We disagree with Dr. Chestnut's conclusion that use of epidural anesthesia does not increase the overall incidence of operative delivery because he excluded most of his cesarean sections.

Many studies conclude that the frequency of instrumental delivery increases with epidural analgesia.[4] Since many obstetricians are less likely to attempt forceps delivery because of medicolegal concerns, an increase in cesarean section results. Dr. Chestnut continues to argue that use of epidural analgesia does not cause an increase in forceps delivery.[5] This is interesting in view of his own randomized prospective study that unequivocally demonstrated that epidural analgesia does increase forceps delivery (21/40 vs 11/40, $p < 0.05$).[2]

Dr. Chestnut is concerned because our retrospective study[1] may "inappropriately discourage obstetricians and patients from using the most effective method of

intrapartum analgesia." We remind Dr. Chestnut that there are many institutions in the United States and in other countries that continue to do well without intrapartum epidural analgesia and in fact have quite low cesarean section rates. Of more concern to us is the possibility that there may be many unnecessary cesarean sections because of epidural analgesia, perhaps not at the University of Iowa, but at other hospitals that do not have the interest, understanding, and expertise of Dr. Chestnut.

We agree with Dr. Chestnut in that prospective studies are superior to retrospective studies, and need to be performed. We do not think that our ethical considerations portray a "lack of conviction" on our part. We have no ethical concerns with Dr. Chestnut's prospective studies. However, to accurately assess the effect of intrapartum epidural on cesarean section rates, patients must be randomized to "epidural" and "no epidural groups" before labor or in early labor. This is the study that should be done, and it would pose significantly different ethical concerns than those of Dr. Chestnut's studies.[2, 3] We wholeheartedly encourage such a study and think that our retrospective studies will lend further support for an investigational research board approval.

Accuracy of apical four-chamber view as screen for congenital heart disease

To the Editors: Please allow me to recount a recent experience of the usefulness of the apical four-chamber view of the heart as a screening test for congenital heart disease in pregnancy.

A 23-year-old patient had one of the first early repairs of a congenital heart defect of severe endocardial cushion disorder at 5 years of age. After operation she required permanent installation of a pacemaker. The patient was first seen at 23 years of age, married with an elective pregnancy 15 weeks from the last menstrual period and requesting a "reassurance" fetal health check.

A detailed fetal anatomy survey revealed no abnormalities of the head, body, spine, arm, legs, and feet; measurements were consistent with dates. The patient was previously immunized with rubella titer. We were unable to obtain an apical four-chamber view of the heart. Ultrasonography of the heart was repeated 5 days later with the assistance of a pediatric cardiologist experienced in fetal echocardiography, by dates and ultrasonographic size at 16 weeks of gestation.

A detailed fetal heart evaluation with multiple scan planes of orientation confirmed abnormal heart anatomy with a delineation of the right ventricle with pulmonary outflow tract well visualized, right atrium, left atrium, hypoplastic left ventricle (none seen), atresia of the aortic root, and aortic arch.

Genetic amniocentesis was performed. However, on the basis of the abnormal ultrasonographic findings, the couple elected genetic termination of pregnancy. Verification of the heart anomaly was not possible by dilatation and evacuation; chromosomes were normal.

This case has several interesting aspects. It demonstrates that it is possible to screen for significant severe (in this case, fatal) congenital heart defect(s) by the inability to obtain a "normal four-chamber image."[1] It further shows continuing improvement in the sensitivity that can be achieved, particularly from the continuing improvements in real-time ultrasound imaging (equipment used: General Electric model RT 2800, recently upgraded to 3200, with a 5.0 MHz curve probe). In this case, this sensitivity and the specificity that was obtained both by the initial four-chamber view screening examination followed by the detailed fetal echocardiographic evaluation, permitted early prenatal diagnosis and enabled the couple to exercise their reproductive option while still in the early second trimester of pregnancy.

The recurrence risk for endocardial cushion defect is said to be 2.9%.[2] It is usual to give couples, when the mother herself has a congenital heart defect, an empirically derived recurrence risk of 10% to 15%. Nora[3] states "A major concern in ECD is that when it is familial, it may be high-risk [type C or Mendelian]. Therefore, we give a low recurrence risk of 2% if there is one effected first degree relative, but a high risk [50%] if there are two first degree relatives with the disease."

For this couple, in the next pregnancy prenatal diagnosis genetic counseling recurrence risk must be considered to be 50%, and they were so apprised of that high-level risk.

Is meconium aspiration an intrauterine event?

To the Editors: The report of Rossi et al. (Rossi EM, Philipson EH, Williams TG, Kalhan SC. Meconium aspiration syndrome. Intrapartum and neonatal attributes. AM J OBSTET GYNECOL 1989;161:1106-10) describing intrapartum factors that could assist the obstetrician in prediction of the occurrence of meconium aspiration syndrome prompted us to review similar published work in this critical area. During the last few years the obstetric and pediatric community believed that meconium aspiration syndrome could be prevented. This belief was based on (1) the assumption that meconium aspiration is a postnatal event, (2) that nasal-oropharyngeal DeLee suctioning of meconium before the delivery of the chest as described by Carson et al.[1] should prevent meconium from being drawn into the tracheobronchial tree during the first few breaths, and (3) the excellent results obtained with this technique by Carson at her institution. However, although no one has yet confirmed their work, the paper has become a landmark document when meconium aspiration syndrome developed in infants. Lawyers have extensively used it to prove that if the meconium aspiration syndrome developed, it was because of lack of adequate suctioning by the obstetrician.

The work by Rossi et al. provides us with data to support the possibility of an intrauterine mechanism of meconium aspiration. Among the 16 infants with aspiration of "thick" meconium, 50% (eight infants) did not "breathe" before intubation and suctioning in the delivery room. If they did not cry or breathe before suctioning, then we could speculate that meconium was below the vocal cords before delivery. Ten of 22 infants with meconium aspiration syndrome did not breathe before intubation and suctioning. If their airways were properly suctioned before the delivery of the chest, it is unlikely they aspirated meconium after birth, supporting the hypothesis that meconium aspiration is an intrauterine event. Intrauterine aspiration may be the rule rather than the exception. Four infants died as a result of severe meconium aspiration syndrome and persistent pulmonary hypertension despite suctioning with a DeLee apparatus and endotracheal suctioning of the upper airway. Suctioning failed to prevent meconium aspiration syndrome and persistent pulmonary hypertension in this study.

Our previous work[2] prospectively studied the effect of DeLee and tracheal suctioning on the incidence of meconium aspiration syndrome. In a series of 755 infants with meconium-stained fluid born during the 12 months of the study year (1983), the incidence of meconium aspiration syndrome was 2% and DeLee tracheal suctioning was routine. This incidence was not different from that seen in a retrospective review of a similar group of 742 infants born in a previous year (1975) when such suctioning was not routine. Suctioning did not prevent meconium aspiration syndrome or persistent pulmonary hypertension.

According to Rossi et al., "A history of thick meconium, the absence of fetal cardiac accelerations and tachycardia on FHR monitoring, umbilical artery pH $\leq$ 7.15, Apgar scores $\leq$5 at 1 and 5 minutes and meconium in the trachea correctly predicted 50% of the infants who require neonatal intensive care unit admission for meconium aspiration syndrome." I suggest a different interpretation of their data. Their aim was to identify predictors for meconium aspiration syndrome, but the factors they identified as predictors of meconium aspiration syndrome are, indeed, consequences of meconium aspiration syndrome. These predictors are actually clinical indicators that meconium aspiration syndrome is present at birth and probably began in utero. In our study,[2] we estimate that during the study year meconium aspiration syndrome developed in 75% of infants while still in utero. In utero aspiration could provide an explanation why meconium aspiration syndrome is not completely preventable despite routine DeLee suctioning.

In summary, we agree with the data of Rossi et al. and only disagree in the interpretation of their findings. We believe their data further support that meconium aspiration syndrome is a prenatal rather than a postnatal event. This concept has medical-legal implications. It should help to dispel claims by plaintiffs' attorneys that meconium aspiration syndrome is "always" a result of inadequate obstetric and/or pediatric suctioning at birth. Thus meconium aspiration syndrome is a disease that cannot always be prevented because its pathophysiologic characteristics are still not completely understood.

Horacio S. Falciglia, MD
Perinatal Center, Department of Pediatrics, Good Samaritan Hospital, Cincinnati, OH 45220

REFERENCES

2. Falciglia HS. Failure to prevent meconium aspiration syndrome. Obstet Gynecol 1988;71:349-53.

Reply

To the Editors: We agree with Dr. Falciglia and would like to reemphasize that meconium aspiration syndrome does not necessarily occur after birth and thus cannot be entirely prevented by clearing of oropharynx or suctioning "below the cords" at birth. Our study and that of Dr. Falciglia have demonstrated that, particularly in the severe cases, meconium aspiration syndrome with respiratory decompensation occurred despite appropriate clearing of infant's airway at birth. All these indications point to the occurrence of meco-

nium aspiration before birth—in utero. Dr. Falciglia disagrees with our interpretation of data. We do not believe that there is any disagreement. According to our data, a history of thick meconium, the absence of fetal cardiac acceleration, fetal tachycardia, a low cord pH, and low Apgar scores indicate that intrauterine fetal distress has occurred with aspiration of meconium and that the syndrome of meconium aspiration with respiratory compromise will develop in 50% of such infants. Thus the disagreement is only in semantics rather than the concept of aspiration of meconium in utero.

We believe that these concepts are very important, both from the medicolegal viewpoint and for the clinical care of these infants.

Cefotetan and the lack of associated bleeding

To the Editors: Although methods designed to decrease excessive hospital and patient costs are necessary and we admire the attempt by Briggs et al. to evaluate the necessity of aminoglycoside levels in the postpartum woman (Briggs GG, Ambrose P, Nageotte MP. Gentamicin dosing in postpartum women with endometritis. Am J Obstet Gynecol 1989;160:309-13), their conclusions are not valid because of limitations in the study design.

Nephrotoxicity and ototoxicity are serious consequences of elevated or prolonged aminoglycoside serum concentrations, and these problems have been well-documented.[1,2] Fortunately, they occur only rarely and can usually be prevented through careful monitoring of serum levels and renal function.[3]

For a predominantly healthy population, such as postpartum women, the incidence of renal, and to a lesser extent, auditory dysfunction, secondary to toxic aminoglycoside is rare and is estimated at maximum to be in the order of 1 in 50 and 1 in 100, respectively.[4] A statistically significant difference between two regimens attempting to evaluate protocols monitoring such toxicity would require a minimum of 2,220 and 4,507 patients, respectively, (to discover a doubling of toxicities with a p value of <0.05 and power of 80). Therefore the conclusions by the authors that the monitoring of serum aminoglycoside levels is unnecessary cannot be substantiated by the number of patients evaluated in their study.

In the 60 patients evaluated, five patients with elevated aminoglycoside levels and the threat of renal damage would have been needed to demonstrate a significant difference (Fisher's exact test). The definition of renal dysfunction is poorly defined in the study and does not state if patients with diabetes or preeclampsia are to be included in their new proposal. Thus, although we agree with the authors that the risks are low and expenses appear prohibitive, the abandonment of aminoglycoside serum measurements is as yet unsubstantiated, with potentially dangerous consequences. We wonder if the authors would have drawn the same conclusion if permanent deafness or severe renal toxicity necessitating lifelong dialysis had developed in the sixty-first patient enrolled.

Perhaps the answer to the expense of monitoring is to avoid or limit use of aminoglycoside, either by proper culturing of infected sites to document the need for aminoglycoside use or with further investigation into the utilization of several of the extremely effective broad-spectrum cephalosporin or monobactam agents.

Reply

To the Editors: Faro and Martens' comments on patient safety are legitimate concerns and we welcome the opportunity to respond to these issues. However, we can find no evidence, either in our patients or in the literature, that otherwise healthy postpartum women with endometritis suffer a 1% to 2% incidence of renal or auditory toxicity when treated with short courses of gentamicin. Moreover, our conclusions were not based on changes in serum creatinine levels, and thus the calculations made by them for sample size do not apply to our study design.

Since 1980 we have treated approximately 2000 women with gentamicin in the postpartum period. Serum creatinine values were initially obtained at the start of therapy and then every 2 days while the patient was receiving gentamicin. Approximately 5 years ago, because we had never observed a potentially toxic increase in the repeat creatinine values, we lengthened the time interval to every 3 days. Throughout this time we have used the generally accepted principle that a rise in serum creatinine of 0.5 mg/100 ml or greater from a normal baseline was an indication of nephrotoxicity.[1] Perhaps we have been fortunate, but we have yet to detect a single instance of nephrotoxicity with this criterion. In our study, 28 of 56 women had a repeat serum creatinine value determined either because therapy exceeded 3 days or because their initial creatinine value was greater than 1.0 mg/100 ml. In eight patients the repeat creatinine value was 0.1 mg/100 ml higher than the initial value, and in three patients the repeat number was 0.2 mg/100 ml higher (0.5 to 0.7 in two

and 0.7 to 0.9 in one). In seven women the repeat serum creatinine value was the same as the initial value, and in 10, the value decreased between 0.1 and 0.4 mg/100 ml. Moreover, over the past 10 years we have selectively determined gentamicin serum levels in postpartum women as specified in our study. During this period approximately 400 women have had levels determined during their therapy. None of these patients had peak or trough concentrations above 10 or 2 μg/ml, respectively.

Our experience with gentamicin dosing in postpartum women strongly supports the four conclusions of Whelton[1] in 1985, although this reference and the other three cited by Drs. Faro and Martens do not include obstetric patients. First, nephrotoxicity or ototoxicity does not occur during the first 1 to 2 days of "major overdosing" if the renal function was initially within normal limits.[1] Second, if possible, courses of aminoglycosides should be restricted to less than 10 days.[1] In our study the range of therapy in 54 patients was 1.33 to 4.42 days (mean, 2.7 ± 1.2 days). Two patients were treated for longer times: 6.32 and 6.33 days, respectively. Our practice has always been to determine levels of any patient treated for 7 days or longer. Third, in patients with normal renal function, a dose of 1 to 2 mg/kg body weight every 8 hours provides appropriate serum levels.[1] Our recommendation of 1.75 mg/kg for average-size women with documented rapid clearance fits within Whelton's range. Fourth, serum drug monitoring should be undertaken after 5 to 7 days of therapy, especially in high-risk patients, because this is when the toxic effects of aminoglycosides are most likely to occur.[1] Except that our patients were women, none could be classified as "high risk" (refer to Whelton, page 73, for his characteristics of patients with clinical risk factors for aminoglycoside nephrotoxicity).

On the basis of our 10-year experience with this patient population, and the conclusions cited in the current literature for patients in general, we believe our recommendations are valid. The use of pharmacokinetic dosing principles in these patients is the best method to ensure that appropriate doses are being administered. However, we recognize that, no matter how desirable, these methods are not always available to the clinician. Thus, rather than replace an inexpensive, effective drug with antibiotics that are much more expensive, we chose to recommend a simple, cost-effective dosing method. We do believe, however, that serum drug level monitoring is mandatory for any patient with renal impairment or abnormal vascular volumes (such as patients with diabetes and preeclampsia), for women whose body heights or weights are much different than average, and for any patient receiving gentamicin for 7 days or longer.

Ultrasonographic guidance for central venous access

To the Editors: Lee et al. described the use of real-time ultrasonography to localize the internal jugular vein and guide the cannulation required for pulmonary artery insertion (Lee W, Leduc L, Cotton DB. Ultrasonographic guidance for central venous access during pregnancy. Am J Obstet Gynecol 1989;161:1012-3). In 1986 Yonei et al.[1] reported using this technique for 160 patients without failure or complications. The anatomy as visualized by ultrasonography was described earlier.[2] The efficacy of ultrasonographically guided cannulation of the internal jugular vein was evaluated by Mallory et al.[3] They used a 5 MHz small parts, near-focus transducer inserted into the thumb of a sterile glove, size 8½. Povidone iodine ointment was used as the acoustic coupling medium. Under ultrasound guidance 12 of 12 patients had successful catheterization whereas significantly fewer (11 of 17) had successful catheterization with the conventional technique without ultrasound guidance. The mean (±SD) number of passes to cannulate the vein was 1.7 (±0.97) with ultrasonography versus 2.94 (±1.73) without ultrasonography, a significant difference. Obstetric patients who require critical care are likely to benefit from management incorporating techniques initially described by intensivists.

Reply

To the Editors: The additional information that Dr. Greenspoon offers through his critical care medical background is greatly appreciated. Obstetricians should be able to extend these experiences to patients who require invasive hemodynamic monitoring. This should remind perinatologists who use ultrasonographic guidance for percutaneous umbilical artery sampling that the same principles can also be applied to much larger vessels in critically ill gravid women.

Fetal heart rate monitoring during cesarean section

To the Editors: I read with interest and dismay the article by Petrikovsky et al. (Petrikovsky BM, Cohen M, Tancer L. Usefulness of continuous fetal heart rate monitoring during cesarean section. AM J OBSTET GYNECOL 1989; 161:36-7).

In my opinion their suggestion to leave the scalp electrode attached during cesarean sections for fetal distress represents poor surgical judgment. Removing wires contaminated by stool and vaginal secretions through the uterus and maternal abdomen can only serve to increase the infection rate in the mother without demonstrable benefit to the fetus.

In the authors' first case in which the surgeons encountered extensive abdominopelvic adhesions, it is difficult for me to imagine how the operators would have responded to a decreased fetal heart rate. Would they have cut through the maternal bowel and bladder to rescue the fetus? I would hope that the surgeons exercised appropriate care and skill while progressing as rapidly as possible with the dissection, as any good surgeon would do.

In their second case, as in all cesarean sections for fetal distress, the procedure should have been done as deftly and expeditiously as possible. As the case demonstrates, the return of the heart rate to normal is not a license to dawdle.

The authors' suggestion that undue surgical haste causes fetal and maternal injury is valid. However, an experienced and competent surgeon would never move so quickly as to endanger the mother in order to deliver the fetus a few seconds sooner. It is proposals such as those made by the authors in this article that perpetuate the myth (reality?) that many obstetricians are not "real" surgeons. By rejecting their proposal, obstetric surgeons can avoid perpetuating that myth.

Reply

To the Editors: We would like to respond to Dr. Dunn's comments.

First, we regret causing her dismay, which could have been avoided if she had read our initial publication (reference 2 in the article), from which we quote, "The lower extremities were 'frog legged' so that the scalp electrode could be removed 'from below' as the fetal vertex was about to be delivered."

Second, in case 1, had urgency been necessary, "meticulous and time-consuming surgery for identification of the vesicouterine fold and dissection of the bladder flap" would not have been carried out. A classic incision would have expedited delivery of the presumed compromised fetus.

Finally, we agree that "undue surgical haste is never wise." However, a "real" surgeon knows that there are options to any surgical approach that permit a flexible response to the needs of the moment.

Can anesthetic-related maternal mortality be reduced?

To the Editors: anesthesia continues to be a prominent cause of maternal mortality, accounting for approximately 10% of pregnancy-related deaths.[1] At least 90% of maternal deaths are attributable to general anesthesia, primarily as a result of failed endotracheal intubation or pulmonary aspiration of gastric contents,[1] despite the fact that more than 50% of cesarean sections in the United States are performed with regional (spinal or epidural) anesthesia.[2] May and Greiss (May WJ, Greiss FC Jr. Maternal mortality in North Carolina: A forty-year experience. AM J OBSTET GYNECOL 1989;161:555-61) report comparable statistics for anesthetic-related deaths (of which *all* were attributable to use of general anesthesia) and further state that "anesthetic complications represent the most clearly identifiable area for prevention." I certainly agree with this viewpoint, but I would like to comment on a statement by Dr. J. Bruce Taylor in the Discussion section of this article.

Dr. Taylor stated that "We may very well have reached an irreducible minimum in anesthetic-related deaths with more complications occurring now from morbid obesity than from the gravid state. (Three of four deaths were noted in markedly obese patients.)" This contention is supported by May and Greiss, who found no change in deaths from anesthetic complications from 1981 to 1985 compared with 1976 to 1980. However, I think that increased use of regional anesthesia, which rarely results in maternal mortality, will almost certainly reduce the number of deaths from anesthesia because regional anesthesia does not eliminate the parturient's ability to protect her airway from pulmonary aspiration of gastric contents and obviates the need for endotracheal intubation (for which failure to accomplish the procedure, in obstetrics, has been reported to occur in 1 in 300 attempts,[3] with difficulty encountered in 5% of cases[4]). I also believe that the morbidly obese parturient is especially suited for regional anesthesia.

Obese individuals, because of more difficulties with intubation and higher gastric volume, lower gastric pH, and diminished barrier pressure (lower esophageal sphincter tone minus intragastric pressure) compared with normal patients, are exposed to much greater risks during general anesthesia.[5] The fact that three of the four anesthetic-related deaths reported by May and Greiss resulted from difficult endotracheal intubations in markedly obese individuals attests to the anesthetic

risks involved. I believe, as do others,[5] that regional anesthesia (specifically epidural anesthesia) is the technique of choice for cesarean section in the obese parturient. In addition to eliminating the risks of inducing unconsciousness and performing endotracheal intubation, use of regional anesthesia reduces postoperative pulmonary complications in obese patients.[6] Intraspinal narcotics can be used, and obese individuals who receive epidural narcotics for postoperative analgesia ambulate earlier, suffer fewer pulmonary complications, have shorter hospital stays,[7] and have less respiratory depression than patients who receive parenteral narcotics.[8]

Another situation in which I think increased use of regional anesthesia is appropriate is that of emergency cesarean section for fetal distress. Although many clinicians favor general anesthesia in this situation, use of regional anesthesia (epidural via a catheter already in place, or spinal) results in equivalent or better neonatal outcome, despite the fact that institution of regional anesthesia may (but not necessarily) take longer.[9-11] This is probably because of the fact that general anesthesia compromises uterine blood flow and fetal well-being,[12] in association with enhanced maternal sympathetic nervous system activity from endotracheal intubation[13] and maternal cardiovascular depression from the thiobarbiturate,[12] whereas regional anesthesia blocks sympathetic nervous system activity and improves uterine blood flow (provided adequate fluid preloading is used).[14]

Increased use of spinal and epidural anesthesia for cesarean section should have a favorable impact on anesthetic-related maternal mortality. In my opinion, regional anesthesia is the technique of choice in all situations (including emergency cesarean section and for the morbidly obese parturient) unless an absolute contraindication exists (coagulopathy, infection over the site of needle puncture, maternal hemorrhage with hemodynamic instability, or patient refusal).

Finally, May and Greiss stated that "such circumstances demand the best anesthesia expertise available," referring to anesthetic management of the obese parturient. This statement certainly applies equally to any obstetric anesthetic administered.

Ritodrine infusion and cardiomyopathy

To the Editors: Blickstein et al. (Blickstein I, Zelel Y, Katz Z, Lancet M. Ritodrine-induced pulmonary edema unmasking underlying peripartum cardiomyopathy. AM J OBSTET GYNECOL 1988;159:332-3) have reported a case of cardiomyopathy associated with pulmonary edema in a woman receiving ritodrine. In the patient described ritodrine was infused intravenously at rates of 50 to 100 μg/min continuously for 28 days. No reference was made to evaluation of fetal lung maturity. At 34⅚ weeks, when contractions recurred, the ritodrine infusion rate was increased to 300 μg/min and 3 hours later pulmonary edema developed.

There are several aspects of this case that merit consideration. First, in the case presented, the authors have referred to the cardiomyopathy in this case as being idiopathic in nature. However, it is equally possible that prolonged ritodrine infusion altered myocardial function, leading to the clinical picture of a cardiomyopathy. Catecholamines infused for prolonged periods or in high doses can cause myocardial necrosis and cardiomyopathy.[1,2] Therapeutic concentrations of

β-adrenergic receptor stimulations in vitro or in vivo cause specific lesions in human fetal or neonatal myocardium.[3, 4] In view of these observations one cannot exclude the possibility that myocardial dysfunction in this patient was caused by rather than unmasked by prolonged ritodrine infusion.

A second aspect of this case relates to the aggressive use of ritodrine or any tocolytic. Is it appropriate to infuse a drug such as ritodrine continuously for 28 days? Is it appropriate to attempt to reinhibit labor in a patient such as the one described, who has recurrent labor at 34⅚ weeks? The authors indicate that three attempts were made to switch to oral ritodrine after the first episode of preterm labor was treated with intravenous medication. The authors do not indicate the dosage of oral ritodrine used in this transition. We have shown in pregnant women that peak plasma concentrations of ritodrine after a 20 mg dose average only 8 ng/ml, yet the concentration achieved during an infusion of 50 μg/min is approximately 23 ng/ml.[5, 6] Thus, when oral ritodrine therapy is used to sustain labor inhibition after intravenous infusion, recurrent labor can occur since the plasma concentrations during oral therapy are much lower than after intravenous therapy. Even with repeated oral doses of 20 mg, the peak and trough concentrations of ritodrine are only 18 and 11 ng/ml, respectively.[7] These concentrations are unlikely to sustain labor inhibition, and, as we have demonstrated, a ritodrine dose of 20 mg every 4 hours is significantly less effective in this regard than is terbutaline 5 mg every 4 hours.[5] We[8] and others[9] have documented that administration of β-agonists for prolonged periods leads to a rapid loss of myometrial β-adrenergic receptors and a loss of tocolytic efficacy. These receptor effects coupled with a dosage regimen that provides low plasma concentrations place the patient at high risk for recurrent labor.[5] These circumstances also may account for the inability to "wean" patients from parenteral to oral therapy. Rather than using higher oral doses, some physicians have chosen to administer a tocolytic agent intravenously for prolonged periods. The risks associated with such therapy have not been adequately evaluated. Besides producing metabolic and cardiovascular derangements, which have been characterized with short infusions, prolonged infusion of these agents may produce other effects such as the one described by Blickstein et al. Also the impact of prolonged bed rest must be assessed, particularly in view of the known effects of bed rest on bone demineralization, muscle wasting, thromboembolic disease, and maternal emotional and psychological state. The case presented by Blickstein et al. suggests that overly aggressive use of tocolytic agents should be discouraged.

Reply

To the Editors: We thank our distinguished Pittsburgh colleague for the informative critique. He suggests an alternative explanation for cardiac failure, namely, secondary cardiomyopathy allegedly caused by ritodrine cardiotoxicity. He cited sympathomimetic-induced cardiac necrosis and myopathy with rather nonspecific agonists or with ritodrine itself on immature fetal and neonatal tissue. However, there are no similar reports in adult or pregnant patients. On the other hand, several studies evaluated echographically the cardiovascular effects of ritodrine tocolysis. Hosenpud et al.[1] studied the left ventricular size and performance during ritodrine tocolysis and found that left ventricular end-diastolic dimensions were unchanged. M-Mode echocardiography performed before and during intravenous β-adrenergic agonist tocolysis found decreased left ventricular dimension and no changes in left atrial dimension.[2] Hadi et al.[3] found similar cardiovascular effects. Interestingly, in half of the patients in the latter study, pulmonary capillary pressure exceeded the threshold for the development of pulmonary congestion but none had clinical manifestations. It is therefore expected that some evidence of dilative cardiomyopathy has to be seen before ritodrine is included among

the potentially cardiotoxic agents (such as the anthracycline doxorubicin, high-dose cyclophosphamide, 5-fluorouracil, tricyclic andidepressants, and lithium. None has been observed thus far.[1-3]

Next, the commentator questions the logic in prolonged intravenous ritodrine treatment. There is no doubt that myometrial adrenergic receptor desensitization does occur. Using the lowest effective ritodrine dose titrated clinically to the presence of uterine contractions and maternal tolerance, we are able to arrest labor effectively without monitoring plasma levels of ritodrine, as described in our case report. In our exceptional case, cardiac deterioration must have been insidious and probably unpredictable. In a similar case, subendocardial ischemia on electrocardiography that was found during ritodrine tocolysis resulted from a large left atrial myxoma.[4] Obviously, in both cases ritodrine alone could be blamed for the cardiac complication and the correct diagnosis would have been missed without echocardiography.

The dangerous connotation attributed by the commentator to aggressive use of tocolytic agents must be seen in proportion. There is certainly no place for injudicious and unattended ritodrine treatment. In contrast, careful patient selection combined with intensive monitoring[3] may result in higher rates of successful labor arrest with rare cases of severe side effects.

Ethics and routine ultrasonography in pregnancy

To the Editors: We disagree with the opinion of Chervenak et al. who argue that prenatal informed consent for sonogram should become an accepted indication for obstetric ultrasonography (Chervenak FA, McCullough LB, Chervenak JL. Prenatal informed consent for sonogram: An indication for obstetric ultrasonography. Am J Obstet Gynecol 1989;161:857-60). After listing our arguments against this proposal, we also direct their and the reader's attention to a randomized trial of routine ultrasonography that we are conducting.

In our experience the majority of patients accept the offer of an ultrasonographic examination. The policy of offering ultrasonography routinely is undesirable for several reasons. The first and most important is that its value in low-risk pregnant women and their infants is unclear. Second, there are potential disadvantages, including false-positive diagnoses and the theoretical risk of adverse bioeffects. Finally, standards of care that are based on patient autonomy in the absence of established benefit create unrealistic expectations of physicians and the health care system, lead to inappropriate legal liability, and may eventually prove to be harmful to patients.

We will briefly expand on these points in turn, starting with the value of routine ultrasonography. The authors state that "established benefits currently outweigh harms" and quote several descriptive studies that report diagnostic advantages of routine ultrasonography. However, they do not refer to six published clinical trials that fail to convincingly demonstrate an improvement in perinatal outcome attributable to routine ultrasonography.[1-6]

Second, with regard to possible harm, current epidemiologic research on ultrasonographic bioeffects is inadequate to rule out adverse consequences of fetal ultrasound exposure. Although we assume that ultrasonography is safe, the lack of direct evidence linking human fetal ultrasonographic exposure with adverse outcomes in existing studies cannot be interpreted to mean that there is no risk.[7,8] Until benefit is shown, this theoretical risk must be considered.

In addition to potential bioeffects, false-positive diagnosis and misdiagnosis with ultrasonography can lead to anxiety and unnecessary intervention. Case reports of misdiagnosis of congenital anomalies illustrate the importance of accuracy in prenatal ultrasonography.[9] Mistakes are more likely in the general use of ultrasonography since accuracy is expected to be less than that reported by experts. Also, the predictive value of a positive test is lower in screening programs because of the low prevalence of abnormalities in low-risk populations.[10]

Finally, if we accept the authors' argument that routine ultrasonography should be offered with informed consent, then the same reasoning should apply in other circumstances. The logical extension of this reasoning is that all diagnostic procedures and therapeutic interventions of uncertain value should be offered to each asymptomatic, apparently healthy patient provided they are believed to be without significant risk. Furthermore, physicians could be legally liable for not doing so. Neither physicians nor the health care system could possibly meet this expectation. Even if they could, it may result in harm for patients. Rather, we agree with Elias and Annas[11] that "the welfare of individual patients remains the central concern in the setting of practice standards."

One of the authors' rationales for invoking the principle of autonomy to justify offering every patient an ultrasonographic examination is the assumption of

Chervenak et al. that "conclusive scientific data" on its value is not available now nor will it be "in the foreseeable future." We are attempting to produce conclusive scientific data on the value of routine ultrasonography. The Study of Routine Antenatal Diagnostic Imaging with Ultrasound (RADIUS) is a multicenter, randomized clinical trial comparing routine ultrasonography with usual prenatal care. RADIUS is funded by the National Institute of Child Health and Human Development. The primary aim of RADIUS is to determine the impact of routine ultrasonography on perinatal morbidity and mortality. The trial is designed to avoid the methodologic deficiencies of previous trials, particularly inadequate sample size and the use of ultrasonographic examinations with limited content by inexperienced ultrasonologists.[12] As of this writing, we have randomized approximately 65% of the 15,500 patients we estimate that we need for our study. Our hope is that the RADIUS trial will provide evidence needed to resolve the current uncertainty about routine ultrasonography.

If research can establish a beneficial impact of routine ultrasonography on pregnancy outcome, then physicians should offer it to their patients (including discussion of the potential benefits and risks). Until then, we continue to agree with the conclusions of the National Institutes of Health Consensus Conference on Ultrasound Imaging in Pregnancy and the American College of Obstetricians and Gynecologists that a critical review of the scientific evidence indicates that the value of routine ultrasonography is unclear.[13, 14] These authors' ethical argument that patient autonomy justifies offering ultrasonography routinely would lead to unrealistic expectations of physicians and the health care system, cause an inappropriate legal liability, and may be harmful to patients. It would be ironic and inappropriate to create a standard of care that obligates physicians to offer their patients a procedure of uncertain value when the obligation to provide access to basic prenatal care to all women has not yet been accepted in our society.

Reply

To the Editors: We appreciate the interest of Ewigman et al., who raise a number of criticisms of our proposal that prenatal informed consent for sonogram (PICS) should become an accepted standard for obstetric ultrasonography. We believe that these criticisms can be successfully addressed.

First, we did not make direct reference to the six published articles because of limitations on the number of references in a Clinical Opinion article. We referred to the largest series in the literature.

Second, these trials and the approach of Ewigman et al. focus only on certain beneficence-based clinical considerations, for example, improvement in perinatal outcome. They neglect the importance and relevance of the ethical principle of respect for autonomy, and therefore of enhancing the autonomy of pregnant women. Thus their approach is conceptually incomplete from the perspective of ethics.

Third, we do consider the risks of ultrasonography and argue that, when considered in contrast to the benefits of routine ultrasound, the beneficence-based *balancing* of risks and harms is uncertain. The risks are theoretical, whereas the benefits that we identify can be established independently of the RADIUS clinical trial (e.g., detection of many unsuspected fetal anom-

alies in time to affect obstetric management[1, 2]). We argue that when the beneficence-based balancing of benefits and harms is uncertain *and* when significant values for the patient are at stake (as they are, for example, when termination of pregnancy for an anomalous pregnancy is a possibility), it is reasonable in clinical practice to employ respect for the autonomy of the patient as the deciding ethical principle. Moreover, doing so positively enhances the autonomy of the pregnant woman. Our approach is thus immune to the *reductio ad absurdum* that Ewigman et al. allege, because we are not defending the application of respect to autonomy to decide the use of medical interventions of "uncertain value" but only to decide the use of medical interventions for which there is no decisive beneficence-based balancing of benefits and harms but for which benefits of *certain* value exist. It cannot be emphasized enough that ultrasonographic detection of many fetal anomalies at an early gestational age to offer pregnancy management options is a certain, not an uncertain, value at this time.[1, 2] PICS thus escapes the brunt of the most powerful criticism that Ewigman et al. advance against it.

By opposing PICS Ewigman et al. are in effect advocating withholding from pregnant women information about this *certain* value of routine utlrasonography, a troubling form of paternalism. We strongly advocate that pregnant women now, not at some point in the future, be given this and other pertinent information so that they can undertake their own balancing of the certain value and the uncertainties of routine ultrasonography.

Fourth, Ewigman et al. are correct that accuracy in ultrasonography is a crucial consideration, but this is already the case. This is because of the increasingly widespread use of ultrasonography in obstetrics, quite independently of whether PICS succeeds in becoming a standard of care. The ethical issues here can be succinctly stated: (1) only individuals qualified to perform ultrasonographic examinations should perform them; (2) the informed consent process should include information about the possibility of false-negative and false-positive diagnoses, even when ultrasonography is performed by a competent examiner and interpreter. Both points simply underscore what we stated in our article defending PICS.

Finally, the correspondents criticize us for claiming that there will be an "absence of conclusive scientific data . . . in the foreseeable future" because the RADIUS trial is "attempting to produce conclusive scientific data on the value of routine ultrasonography." Dr. Ewigman kindly provided us with a copy of the RADIUS protocol, and our study of it indicates that the primary research questions of the study concern perinatal mortality and morbidity, with maternal morbidity and the diagnostic accuracy of ultrasonography among the secondary research questions. It is hoped that RADIUS will yield conclusive (i.e., unambiguous) data on its research questions, an unusual occurrence in clinical trials. Even if it were to do so, RADIUS would not totally settle the beneficence-based balancing of benefits and risks because considerations of perinatal outcome and maternal morbidity are not the entire beneficence-related story. For example, fears of unknown harms and benefits of reassuring examinations are significant beneficence-based factors, even if they are difficult to quantify.

It is hoped that one result of RADIUS will be to put the beneficence-based calculus on more reliable grounds. RADIUS is thus best viewed as permitting PICS to be enriched by information of scientific reliability about perinatal and maternal outcomes, thereby replacing less reliable information about these outcomes. RADIUS is not designed to show that the broader beneficence-based balancing of benefits and risks can be conclusively settled one way or another. There will therefore remain a decisive role for the exercise of the pregnant woman's autonomy to determine the balance that is most consistent with her values for her pregnancy. In summary, PICS should be the standard of care for the routine use of obstetric ultrasonography. The data obtained from the RADIUS project will enhance, not replace, this concept.

Amnioinfusion and prevention of meconium aspiration syndrome

To the Editors: The article by Sadovsky et al. (Prophylactic amnioinfusion during labor complicated by meconium: A preliminary report. (AM J OBSTET GYNECOL 1989;161:613-7) raises several interesting issues. The incidence of low Apgar scores at 1 minute and 5 minutes did not differ between the amnioinfusion and control groups. A possible explanation for the reduction in need for positive pressure ventilation at birth in the amnioinfusion group is a reduction of the amount of meconium that infants aspirated before delivery. This reduction could have been achieved by diluting thick meconium in the infused normal saline solution. It is also interesting that 29% of the infants in the control group had meconium below their vocal cords despite appropriate suctioning of their oronasopharynx before delivery of the chest, as described by Carson et al.[1] I reported[2] that timing of obstetric DeLee suctioning (whether before or after delivery of the chest) did not influence the presence of meconium below the vocal cords (37% versus 36%, respectively). Using the same approach, Dooley et al.[3] reported a 19% rate of meconium below vocal cords. In this study there was a lack of correlation between variable decelerations and pres-

ence of meconium below vocal cords. It is therefore exciting to me that the rate of meconium below vocal cords could be reduced to 0% by the combination of amnioinfusion and DeLee airway suctioning. These findings truly support the hypothesis that the majority of the cases of meconium aspiration occur "in utero" and before the first breath. If this is the case then meconium aspiration syndrome is as difficult to prevent as fetal distress. Yeomans et al.[4] found that meconium-stained amniotic fluid correlates poorly with the infant's condition at birth as reflected by umbilical cord pH. The "bottom line" is that when a case of meconium-stained amniotic fluid is encountered, the current state of the art does not allow us to predict which infants will develop meconium aspiration syndrome.

In this stagnated research field of meconium aspiration syndrome, amnioinfusion offers hope. We agree with the authors that the true test will come when amnioinfusion is proved to reduce the rate of symptomatic meconium aspiration syndrome. Hypothetically, if these findings were corroborated by other investigators with a larger sample of patients, then further questions remain. (1) How aggressive will we need to be in detecting the presence of meconium in the absence of labor and intact membranes? (2) Should we use the technique of amnioscopy in patients at high risk for meconium-stained amniotic fluid? (3) How soon should amnioinfusion be started after meconium is detected into the amniotic fluid? And finally (4) will amnioinfusion affect the outcome of infants who already had meconium below vocal cords at the beginning of the procedure?

Reply

To the Editors: We thank Dr. Falciglia for his important comments. Indeed, once the amniotic fluid is stained with meconium, aspiration can occur antepartum, intrapartum, or during the infant's first few breaths after delivery. Only the effect of the latter mechanism can be ameliorated by DeLee suctioning as described by Carson et al.[1] Amnioinfusion may decrease the risk of intrapartum aspiration, but will not prevent aspiration that occurred before labor or before the start of the amnioinfusion. We believe that by utilizing this technique further observations may help identify those fetuses who have aspirated meconium before amnioinfusion.

We concur with Dr. Falciglia that certain questions remain unanswered. The appropriate role of prenatal diagnosis of meconium-stained amniotic fluid is yet undetermined. To optimize the efficacy of amnioinfusion, it should be initiated as soon as possible after the intrapartum diagnosis of the presence of meconium. We agree with Dr. Falciglia that a larger sample of patients is needed to confirm our findings.

Although we think that intrapartum amnioinfusion has the potential to decrease the risk of meconium aspiration, this technique should not be regarded as standard obstetric care by the medical community at large until further research demonstrates the safety of this procedure.

Use of serial human chorionic gonadotropin measurements to differentiate between intrauterine and ectopic pregnancies

To the Editors: I read the article by Lindblom et al. (Lindblom B, Hahlin M, Sjöblom P. Serial human chorionic gonadotropin determinations by fluoroimmunoassay for differentiation between intrauterine and ectopic gestation. Am J Obstet Gynecol 1989;161:397) with some bemusement. My colleagues and I showed almost 10 years ago that when serial human chorionic gonadotropin (hCG) monitoring was restricted to a group of patients roughly similar to that studied by Lindblom et al. (our patients were symptomatic whereas those of Lindblom et al. were not) the slope of the log hCG-time regression line provided a useful method of differentiating between symptomatic intrauterine and ectopic pregnancies when other tests, such as ultrasonography and culdocentesis, were nondiagnostic. We estimated the 15th percentile of the distribution of the slope of this regression line to be 0.25 among women with symptomatic but viable intrauterine pregnancies (when natural logarithms were used), and found that the value for the slope was less than this in 87% of women with ectopic pregnancies.[1]

It is salutory to note (although Lindblom et al. failed to point this out) how well these authors' findings agree with our original results, especially because they excluded patients with falling serum hCG values. By our criterion, 17/19 (89%) of their patients with ectopic pregnancies were identified as abnormal, and the false-positive rate was 18% or 27%, depending on whether one wishes to classify cases 23 and 31 (slopes, 0.248) as normal or abnormal. In either event, the difference between these values and our original figures is easily accounted for by sampling variation.

Since our early publications, Pittaway et al.[2] have questioned whether the rate of increase in hCG during the first 6 weeks of pregnancy is truly exponential as it was originally shown to be by Marshall et al.[3] However, Daya[4] and Fritz and Guo[5] have since resolved this question by showing that the log hCG-time relationship is adequately represented by a linear regression line when hCG values are <10,000 mIU/ml (international reference preparation) and <6500 mIU/ml (second international standard), respectively. In short, during the period of gestation in which Lindblom et al. obtained their data, hCG levels increase exponentially.

In an effort to improve the discrimination between normal and ectopic pregnancies, Lindblom et al. computed a number of statistics that are either statistically invalid or involve assumptions about the log hCG-time relationship in early pregnancy that are known to be untrue. What they term the *absolute slope* (final hCG − initial hCG/sampling interval) is nothing more than the slope of the linear regression of hCG (as opposed to log hCG) on time, which does not correspond with the known way in which hCG increases during the period in pregnancy studied by these authors. Their *relative slope* final hCG − initial hCG/initial hCG × sampling interval) also does not correspond with any known probability model for the hCG-time relationship in early pregnancy because it is assumed in the computation that the proportion by which hCG increases per day is constant. This assumption has not been validated by the authors, nor does it accord with what would be predicted by an exponential (or, for that matter, a quadratic) log hCG-time relationship. The *relative slope* obtained under an exponential model would in fact depend on what sampling interval was used. For example, if the initial hCG is 500 and the doubling time is constant and equal to 2 days, the value obtained for the relative slope would be 0.41, 0.5, 0.61, 0.75, and 0.93, respectively, for sampling intervals of 1, 2, 3, 4, and 5 days.

However, the most questionable aspect of the authors' analysis is the one they recommend for clinical use, namely, the putative regression relationship between the absolute slope and the initial hCG value, which the authors claimed allows better discrimination between ectopic and normal intrauterine pregnancies. But, because the initial hCG value features in both the independent and the dependent variable, a spurious dependency between the two variables is introduced that invalidates the analysis. This is easily illustrated by calculation of the absolute slope for identical proportionate increases in the serum hCG at two different initial hCG values. Suppose that the serum hCG increases by 80% over a 2-day period. If the initial hCG is 200 mIU/ml this would yield an absolute slope of 80, but if the initial hCG value is 2000 mIU/ml, the absolute slope would be 800. It is easy to see that the slope would increase with initial hCG even if the rate of increase was exponential.

There are other unsatisfactory aspects of the analysis, the most notable of which is that prediction intervals were not constructed around "the discriminatory curve . . .between the two clusters of data points." Without these, it is not possible to predict how well this discriminatory curve would perform in other samples from the same population. Inasmuch as many of the data points lie close to the curve, it is more than likely that the discrimination achieved in the authors' sample of patients would not be reproduced in further sets of data.

To provide a heuristic test of the authors' approach, the absolute slope was calculated for the data previously published by Kadar and Romero.[6] For each patient, it was determined whether the absolute slope predicted from the equation derived by Lindblom et al. ($y = 12.31 \cdot x^{0.46}$) was greater or less than the observed absolute slope. The hCG score proved to be abnormally low in 25/34 (74%) of our ectopic pregnancies and to be normal in 38/41 (93%) of normal pregnancies. The specificity of our criterion was 37/41 (90%) and the sensitivity was 27/34 (80%).

These findings show a very important principle of medical testing. If one is trying to distinguish between two groups of persons by means of a test and values among the two groups overlap, it is not possible to improve the test's performance by changing the critical value of the test because test performance is solely dependent on the degree of overlap. Inasmuch as the rate of hCG increase in serum among women with ectopic and intrauterine pregnancies overlaps, one can predict that attempts to improve the effectiveness of serial hCG testing as a means to distinguish between these two conditions that consist simply of changing the test criterion (whether arrived at by legitimate or illegitimate statistical means or arbitrarily) are inevitably doomed to failure.

Reply

To the Editors: We are honored by Dr. Kadar's attention to our article and we have tried to extract the main points in his criticism. Thus, according to Dr. Kadar, our article has the following shortcomings: (1) we failed to point out the similarity between our results obtained with the human chorionic gonadotropin (hCG) score

and those obtained by Kadar et al. in 1981[1]; (2) we assumed that the hCG-time relationship is linear; (3) we did not provide prediction intervals for our discriminatory curve; (4) we applied regression analysis improperly—". . . a spurious dependency between the two variables . . ."; and (5) the good performance of the hCG score was caused purely by chance— ". . . it is more than likely that the discrimination achieved in the authors' sample of patients would not be reproduced in further sets of data."

In reply to this criticism we have the following comments.

The performance of any diagnostic test is highly dependent on the patient material to which it is applied. In the article by Kadar et al.[1] no precise information about selection criteria was provided. Although Dr. Kadar states in his letter that their and our patient groups were "roughly similar," we had no basis for such an assumption. During the past decade Dr. Kadar's group has published >10 papers concerning their approach for analysis of hCG patterns in early pregnancy and their concept of a discriminatory hCG zone. Of all these publications we referred to the one that we considered most readable and relevant.[2]

We explicitly stated that we consider the hCG-time relationship as being nonlinear in viable intrauterine pregnancy. However, *to simplify calculations* we approximated this relationship to be linear over a period of up to 6 days. By use of a sampling interval of 1 to 2 days this error is reduced. Regardless of the mathematic function used to describe the normal increase of hCG in serum in viable intrauterine pregnancies, there is a difference between pathologic and normal pregnancies with regard to the rate of increase in serum hCG, and this difference can be analyzed for differential diagnostic purposes. Because the fitting of mathematic functions to biologic data are always approximations, we believe that there is no single true way to describe the course of a biologic event, such as the hCG increase in early pregnancy. The clinical usefulness of a diagnostic test is determined not only by its validity and pure scientific qualities, but also by its ease of use. Whereas the standards with regard to the former properties must always be high, it is equally important that descriptions and explanations of the tests are intelligible. Otherwise, an original work runs the risk of not being properly cited and the ideas advanced may not be put to use. The following passage cited from Kadar et al.[1] serves to illustrate difficulties of this kind:

Dividing the specificity (86%) by the false-negative rate (13.3%) and multiplying the result (6%) by the intrauterine:ectopic pregnancy incidence ratio enables one to calculate the number intrauterine pregnancies correctly diagnosed for every patient with ectopic pregnancy in whom the diagnosis is delayed beyond 48 hours.

A nomogram is what is needed to use the hCG score. In contrast, to use Dr. Kadar's method one would need a scientific calculator or log tables.

It is true that we have not provided prediction intervals for the discriminatory curve. The validity of the diagnostic test is currently being evaluated in a prospective study of a large patient material. So far, the validity of the test has not declined.

Table I. Results for pathologic pregnancy

	Sensitivity	*Specificity*
Kadar's method	0.89	0.90
hCG score	0.89	0.95

We agree that the initial hCG value features both in the independent and the dependent variable. We disagree with Dr. Kadar's contention that this introduces a spurious dependency. It is obvious that the relationship between daily change and the initial hCG value seen in ectopic pregnancies is different from that seen in viable intrauterine pregnancies. Use of the initial hCG as an independent variable in the prediction of the change in hCG is a permitted method no different from predicting sick leave of a population in 1989 with the use of sick leave in 1988 in the same population as an independent variable.

We compared the performance of the hCG score against that of Kadar's method in our updated material of 160 ectopic pregnancies and 73 viable intrauterine pregnancies. Results we obtained for pathologic pregnancy are shown in Table I. From these results we conclude that in early pregnant patients (hCG <4000 IU/L), the hCG score performs as well as (or even better than) the method of Kadar et al. Inasmuch as the hCG score also is much easier to use, we believe that it constitutes an important improvement in terms of clinical usefulness.

Intracellular sodium levels in pregnant women with hypertension

To the Editors: I am surprised that Sowers and colleagues (Sowers JR, Zemel MB, Poronsteen RA, et al. Erythrocyte cation metabolism in preeclampsia. Am J Obstet Gynecol 1989;161:441-5) placed so much emphasis in their discussion on a laboratory value (parathyroid hormone) that was not significantly different from that of controls.

Besides, in contrast to the authors' negative findings, Tranquilli et al.[1] found an increase in intracellular sodium in pregnant women with hypertension. Even Weissberg et al.[2] whom the authors use as support for their negative findings, suggest that a negative finding "does not rule out the possiblity that subjects within the group might not have important increases in intracel

lular sodium over the course of their pregnancy." Given that the authors found elevated levels of endoxin in the hypertensive group, it would be interesting to learn the intracellular values of sodium in subjects with significantly elevated endoxin values.

Reply

To the Editors: Although increased circulating endoxin may be expected to inhibit sodium-potassium adenosine triphosphatase activity and thereby reduce intracellular sodium levels, our data do not support this. However, our findings are consistent with a previous report that *chronic* exposure to digoxin does not result in reduced sodium pump activity or increased intracellular sodium levels, although short-term treatment does result in these effects.[1]

In addition, we found that both plasma endoxin and erythrocyte sodium-potassium adenosine triphosphatase activity exhibit significant increases during pregnancy.[2] Further, there is a significant positive correlation between the two ($r = 0.72$) rather than the expected inverse relationship, suggesting that the sodium-potassium adenosine triphosphatase exhibits an adaptive response to the high endoxin levels.[2] Thus, these data further support the finding that increased endoxin levels in patients with preeclampsia does not result in a chronic suppression of sodium-potassium adenosine triphosphatase activity and thereby an increase in intracellular sodium levels.

Screening infertile women for subclinical hypothyroidism

To the Editors: Wilansky and Greisman reported an association between menorrhagia and an abnormal thyroliberin (thyrotropin releasing hormone) stimulation test (Wilansky DL, Greisman B. Early hypothyroidism in patients with menorrhagia. Am J Obstet Gynecol

sulted in elimination of menorrhagia. Bohnet et al.[1] reported that subclinical hypothyroidism was found in 20 of 150 infertile women with anovulation or luteal insufficiency. Thus, it is common practice to screen infertile women with the use of thyroid function tests (thyroxine, thyrotropin, triiodothyronine resin uptake, and free thyroxine index).

However, a cursory review of thyroid function test results of infertile women at our institution suggested a low prevalence of abnormal thyroid function test results from such screening. Therefore, we performed a survey to determine the prevalence of subclinical hypothyroidism in a population of infertile women and to ascertain whether routine screening of this population for subclinical hypothyroidism with thyroid function tests, especially thyrotropin measurement, is justified.

We reviewed the records of 210 patients enrolled in our infertility clinic during a 1-year period. None of these patients had clinical or laboratory findings consistent with the presence of overt thyroid disease, thyroid enlargement, or thyroid autoantibodies. We categorized our patients' infertility according to standard clinical criteria. Ovulatory dysfunction was suspected from a clinical history of amenorrhea or irregular menses. This diagnosis was confirmed if the basal body temperature showed a prolonged (≥21 days) follicular phase or a monophasic pattern accompanied by a decreased (<3 ng/ml) serum progesterone concentration or if an endometrial biopsy specimen showed proliferative endometrium. A luteal phase defect was not considered an ovulatory disorder.

Serum from all patients' blood samples were assayed for thyroxine and thyrotropin ("regular" immunoradiometric assay) in the automated radioimmunoassay—high technology instrument (Becton Dickinson Immunodiagnostics, Salt Lake City, Utah).[2] The triiodothyronine resin uptake assay (Nuclear Diagnostics, Troy, Mich.) was performed on all samples and the results were used to calculate the FTI = (thyroxine) × [T_3(RU)/30], where FTI = free thyroxine index, T_3 = triiodothyronine, and RU = resin uptake. Prolactin concentration was determined with the Tandem-R prolactin kit (Hybritech Inc., San Diego, Calif.).

Patients ($n = 8$) with subclinical hypothyroidism were asymptomatic but had an increased thyrotropin concentration (mean thyrotropin ± SD = 8.3 ± 2.7 mIU/L; range, 5.3 mIU/L to 12.3 mIU/L) and thyroxine, triiodothyronine resin uptake, and free thyroxine index values within the normal reference range for these analytes established in our laboratory. It has been previously shown that an increased (5.2 mIU/L < [thyrotropin] < 10.4 mIU/L) thyrotropin concentration in euthyroxinemic patients is commonly associated with abnormal thyrotropin-releasing hormone test results suggestive of subclinical hypothyroidism.[3] At a thyrotropin cutoff value of 5.2 mIU/L (i.e., the upper limit of the normal reference range for thyrotropin concentration established in our laboratory), diagnostic sensitivity and specificity were 71% and 96%, respectively.

(87%) patients with an increased thyrotropin concentration and in 55 of the remaining 202 (27%) women who had a normal thyrotropin concentration. By χ^2 analysis, these distributions were significantly different ($p < 0.001$). Conversely, the incidence of subclinical hypothyroidism in dysovulatory women ($n = 62$; seven with an increased thyrotropin concentration and 55 with a normal thyrotropin concentration) was 11.3%. Prolactin concentrations were normal (mean prolactin ± SD = 6.6 ± 2.3 ng/ml; normal range, 0 ng/ml to 20 ng/ml) in serum samples from all eight patients who had an increased thyrotropin concentration.

Patients with subclinical hypothyroidism are generally asymptomatic and produce suboptimal levels of thyroid hormones that are compensated for by increased output of thyrotropin to maintain euthyroxinemia.[4] This disorder has been estimated to occur in up to 7% of the adult population[5] and is generally considered an innocuous disease, although it has been linked to hypercholesterolemia and impaired cardiac systolic time intervals.[3] In our population of infertile women the incidence of subclinical hypothyroidism was only 3.8%, but in the subset of women with ovulatory dysfunction the incidence increased threefold to 11.3%.

If the diagnostic sensitivity and specificity of a test and the prevalence of disease in a population are known, the positive or negative predictive value of this test can be calculated.[6] With the use of the sensitivity (71%) and specificity (96%) of the thyrotropin test (at a thyrotropin cutoff concentration of 5.2 mIU/L) to predict subclinical hypothyroidism and the prevalence (3.8%) of this disease in our population of infertile women, the positive predictive value is only 41% (i.e., 59% of all patients with an increased thyrotropin concentration will not have subclinical hypothyroidism). However, among dysovulatory women the positive predictive value of the thyrotropin test increased to 68%.

We conclude that in a population of infertile women, subclinical hypothyroidism may be observed occasionally; however, the prevalence of this disease in this group of women is probably no greater than the prevalence in the general population. Even if the diagnostic sensitivity and specificity of the thyrotropin test were increased by use of currently available "sensitive" thyrotropin assays,[2] the low prevalence of subclinical hypothyroidism in infertile women suggests that it may not be cost effective to routinely screen this group of women for this disease. However, in our population of dysovulatory women the prevalence of subclinical hypothyroidism increased threefold. Wilansky and Greisman have proposed "systematic study of thyroid function" in women with menorrhagia. Similarly, our data suggest that it may be prudent to screen dysovulatory women for subclinical hypothyroidism with a thyrotropin measurement.

Reply

To the Editors: We thank Dr. Strickland and colleagues for sharing with us their important and significant observation on subclinical hypothyroidism in persons with infertility, and in particular those with ovulatory dysfunction. We were particularly interested to be informed of the 11% prevalence of hypothyroidism in the ovulatory dysfunctional group and the suggestion to screen dysovulatory women for subclinical hypothyroidism. I wonder whether Dr. Strickland and colleagues have had an opportunity to note the response to L-thyroxine administration in these dysovulatory patients with subclinical hypothyroidism.

The endocrine literature has characterized subclinical hypothyroidism as occurring in two phases. The later phase is that in which there is random thyrotropin elevation. The earlier phase is identified only after administration of thyrotropin-releasing hormone. We showed that whereas within the normal reference range serum thyroxine levels are significantly lower in the early phase than in a control population. If Dr. Strickland's group wished to maximize their recognition of subclinical hypothyroidism a modified thyrotropin-releasing hormone test might be desirable. In some persons with subclinical hypothyroidism, the diagnosis will be missed because the random thyrotropin elevation in early hypothyroid states may be intermittent, similar to the gonadotropic hormone elevation in early ovarian failure.

Finally, because we are talking about clinical manifestation of so-called *subclinical hypothyroidism,* we wonder whether this term continues to be appropriate. We have suggested the term *early hypothyroidism* to replace such terms as triiodothyronine euthyroidism, *compensated hypothyroidism,* and *subclinical hypothyroidism.* Furthermore, we believe that this term may stimulate efforts to clarify the clinical significance of these important phases of developing hypothyroidism.

Study results vary in count-to-10 method of fetal movement screening

To the Editors: We read with interest the article by Moore and Piacquadio (Moore TR, Piacquadio K. A prospective evaluation of fetal movement screening to reduce the incidence of antepartum fetal death. AM J OBSTET GYNECOL 1989;160:1075-80) that concluded that the "Cardiff count-to-10" method of fetal movement screening reduces the prevalence of antepartum fetal death. We recently reported a very large randomized controlled trial[1] that came to the opposite conclusion. There may be a number of reasons for this discrepancy.

It is possible that Moore and Piacquadio's finding may be explained by problems that resulted from imprecision and bias. Their sample size is very small (about 4000 compared with 68,000 in our study). Small trials tend not only to miss finding true effects, but also to overestimate the size of any effect found. (In fact, at a very early stage of our trial, the distribution of antepartum deaths between the counting and control groups looked very similar to that of a small randomized controlled trial by Neldam.[2]) The fact that in Moore and Piacquadio's study the death rate was higher than that expected in the control period and was so much lower during the study period suggests that the pattern may well be a result of random variation over a very short time period, rather than being a true effect of the policy.

The second potential problem is one that arises from bias. The most serious component of this is selection bias. The concern must be that as control and study groups were neither randomized nor contemporaneous, they might differ from each other in respects other than participation in the counting policy. Could the authors reassure readers of the comparability of the groups? Another source of selection bias is that that occurs because of selective withdrawals from the cohorts before the analysis. The fact that the numbers of women in the two 7-month time periods are so different (2519 and 1864) suggests that this may have happened. Was the study group based on "compliers" only? This could give a false picture of the effects of the policy because compliers tend to do better than noncompliers, regardless of whether the management with which they are complying is effective.[3]

The third potential source of bias is that at case ascertainment. Were decisions about the timing of death (i.e., whether the death occurred before or after the onset of labor, or at what gestational age) and about the cause of death made without knowledge of whether the women had their antenatal care in the study or control time period?

Apart from these issues of imprecision and bias, it is possible that special aspects of Moore and Piacquadio's counting protocol may go some way toward explaining their findings. This protocol was applied in the evenings, and their pilot study found that women counted to 10 movements in a very short time (mean 20.9 minutes). This is very much quicker than has been reported elsewhere in the literature.[4] Probably because of this, their rate of compliance was also very much higher than in other studies.

Moore and Piacquadio's replies to these concerns (particularly about bias) may help readers to interpret the study's findings.

Reply

To the Editors: We thank Drs. Elbourne and Grant for their interest in our recent study. We also read with interest the results of a large-scale randomized control trial that came to the opposite conclusion of our study.[1]

With regard to the question of sample size and study precision, we used a χ^2 comparison to contrast the number of deaths that occurred in the control period as compared with that in the study period. As noted in the article, this was statistically significant at the 99% confidence level. We are now able to report a 30-month update in our study, which comprises 5758 patients managed with a count-to-10 method with the use of a 2-hour limit. During this period there have been 21 stillbirths in 5758 births for a fetal mortality rate of 3.6 per 1000. This is still significantly less than the fetal mortality rate in the control period, and indeed approximately half of the fetal mortality rate in the state of California. One of the problems with the study of Grant et al.[1] is that the baseline fetal mortality rate was only 2.67 per 1000. These rates have not been achieved in the United States and may partially explain why the large-scale study failed to show a significant effect.

With regard to the comparability of the groups in the control study period, Naval Hospital San Diego has served the same military dependent population over the past two decades. Demographic surveys during this period have failed to show any drift in the basic obstetric indicators of this population. Moreover, we statistically analyzed all fetal deaths that occurred during our study. Two of the four mortalities occurred before 28 weeks' gestation, one in a patient with no prenatal

care and one in an anencephalic fetus. All deliveries of ≥20 weeks' gestation were used in the denominator.

The study of fetal movement counting with contemporaneous groups is extremely difficult because of the problem of "bleedover." This was addressed in the study of Grant et al.[1] by use of the cluster technique. In our particular patient population, a control group could not be identified that would not have gained access to and readily accepted fetal movement counting practices. Nevertheless, we strongly believe that a fetal mortality rate of 3.6 per 1000 is an enviable rate among middle-class women in the United States.

In our opinion, the largest difference between the study of Grant et al.[1] and ours is the rate of compliance. As documented in our article, 10 fetal movements in the evening are counted within 10 to 15 minutes by most women. Rapid test completion has likely been the major factor responsible for continued high compliance in our population (>93% during the past 30 months). Our study placed value on a sensitive movement alarm signal, whereas the study of Grant[1] chose specificity; unfortunately, this resulted in a significant proportion of patients with decreased fetal movement seen after fetal death.

We believe that an appropriately designed fetal movement criterion should be highly sensitive and identify fetuses at risk that need traditional antepartum testing. Given the marked differences in the two methods, a large-scale, controlled, randomized study of the San Diego count-to-10 method is indicated.

Changes in the incidence of ectopic pregnancy in Hungary

To the Editors: I have read with great interest the recent work of Mäkinen et al. (Mäkinen JI, Erkkola RU, Laippala PJ. Causes of the increase in the incidence of ectopic pregnancy. A study on 1017 patients from 1966 to 1985 in Turku, Finland. Am J Obstet Gynecol 1989;160:642-6), giving account of a more than threefold increase in the rate of ectopic pregnancies in Finland between 1966 and 1985. Their data appear to indicate that the increase of extrauterine gestation has reached epidemic proportions in that country. Noting that Fins and Hungarians, living under markedly different geographic and climatic conditions, both belong to the Finn-Ugor racial group, we thought that it was matter of interest to investigate the changing patterns of the incidence of ectopic pregnancy in our country during the last half a century.

We are inclined to identify three important periods of time in the context of the relevant data. The years of 1946 to 1950 marked the beginning of the use of antibiotics in Hungary. At that time sophisticated contraceptive techniques were not as yet available. During the years of 1964 to 1968 advanced birth control methods were known in Hungary but were not yet used widely in the population. By the years of 1984 to 1988, hormonal contraceptive methods were extensively used and so were virtually all broad-spectrum antibiotics. We found it necessary to use the above yardstick for the evaluation of our data, noting the fact that contemporary treatment of pelvic inflammatory conditions and the use of oral contraception are generally considered significant with regard to the etiology of ectopic gestation.

The rate of ectopic pregnancy in Hungary during the above quoted 5-year periods ranged between 0.45% and 0.54% (Table I). The increase from 450 ectopic pregnancies per 100,000 total pregnancies in 1964 to 1968 to 540 in 1984 to 1988 is significant at the $p < 0.005$ level. The 480 extrauterine pregnancies per 100,000 total gestations in the years of 1946 to 1950 is not significantly less than that noted in 1984 to 1988. (The χ^2 test was used for determining the level of significance.) The difference between the 1946 to 1950 and the 1964 to 1968 rates is negligible. However, the increase by 1984 to 1988 is at the range of 20%. Our data appear to indicate that the increase of the rate of ectopic pregnancy in Hungary was markedly less than that observed in northern Europe and the United States.[1-3]

Table I. Rate of ectopic pregnancies, in comparison with all pregnancies, in course of three separate 5-year periods in Hungary

First 5 yr		*Second 5 yr*		*Third 5 yr*	
yr	*%*	*yr*	*%*	*yr*	*%*
1946	0.36	1964	0.5	1984	0.5
1947	0.39	1965	0.48	1985	0.54
1948	0.5	1966	0.44	1986	0.58
1949	0.55	1967	0.43	1987	0.52
1950	0.6	1968	0.38	1988	0.56
Mean	0.48		0.45		0.54

The cause of the increase in the incidence of ectopic pregnancy is multifactorial. A discussion of the hypothetical explanations for the difference between the observed increase in the rate of ectopic pregnancy between Hungary and Finland is beyond the scope of this short communication.

I thank András Klinger, PhD, Central Statistical Office, Budapest, for his valuable help.

Reply

To the Editors: We thank Dr. Jakobovits for the interest concerning our article.

In his letter Dr. Jakobovits has shown a negligible increase in the rate of ectopic pregnancy in Hungary, which is in opposition to the great increase of ectopic pregnancy in many countries in western Europe and in the United States. He did not endeavor to hypothesize the reasons for this difference, and we do agree that this may turn out to be somewhat difficult. However, at least two obvious differences between Hungary and Finland should be pointed out. First, although the exact figures for Hungary are not available to us, the use of an intrauterine contraceptive device has probably been much more limited in Hungary than in Finland, especially in the 1970s and early 1980s. This could be considered as an additional, yet indirect evidence for the role of the intrauterine contraceptive device in the increase in the rate of ectopic pregnancy. Second, the effect of improved diagnosis also needs consideration. In Finland this may explain some of the increase in the rate of ectopic pregnancy, but to be able to compare Hungary and Finland in this regard, we must know the workup used in Hungary for the diagnosis of ectopic pregnancy in the years of the study, e.g., how widespread the use of highly sensitive pregnancy tests, ultrasonography, and laparoscopy has been.

Incidentally, an interesting observation on the relation between legal abortion and ectopic pregnancy may be made when one is looking at the statistics from Hungary and Finland. The rates of legal abortion in Hungary have been more than fivefold those in Finland. In our study legal abortions did not show any strong association with the increase of the rate of ectopic pregnancy. The comparison of figures from Hungary and Finland again gives indirect support to this observation.

Cerebral palsy and intrapartum fetal acidemia

To the Editors: I believe that the data of Dennis et al. do not warrant the author's conclusions (Dennis J, Johnson A, Nutch L, Yudkin P, Johnson P. Acid-base status at birth and neurodevelopmental outcome at four and one-half years. AM J OBSTET GYNECOL 1989;161:213-20).

Just as Baird's documentation of the interacting social factors that influence health and child-bearing failed to be accepted in America,[1] to speak of "impairment codes" does not have current American obstetric clinical or medical-legal implications. The present issue on this side of the Atlantic is cerebral palsy and its possible relationship to intrapartum fetal acidemia. The authors started with a data base of 1210 cases at term, which should have produced at the most only two cases of cerebral palsy. If only 10% to 20% of cases of cerebral palsy are due to intrapartum fetal distress, I believe the authors whould have to have had access to at least 5000 cases to have one case of cerebral palsy caused by obstetric events. Furthermore, no information is given about genetic factors, which may have a significant role in developmental "impairment."

While the authors spoke of "physiologic acidosis," no mention was made of lactic acid in their discussion. Hendricks[2] noted that fetal difficulty occurred more frequently when maternal lactic acid values failed to increase near term. The literature on lactic acid as a fetal substrate is extensive.[3] Presumably, its production by the placenta has fetal benefits, although it may at the same time contribute to the apparent acidemia of the fetus.[4] Nevertheless, such a metabolic acidemia would not be "physiologic" in that it is highly variable.

Years ago, Kaiser and I[5] showed that altering maternal pH likewise altered fetal pH. In any population of newborns, to attempt to discuss the significance of fetal acidosis in the absence of maternal pH determinations is in my opinion futile.

I continue to believe that the possible role of fetal acidemia will be delineated only when routine maternal and umbilical pH values are obtained on thousands of deliveries. Then, when cases of cerebral palsy occur,

we can accurately determine the significance (if any) of "fetal acidosis."

Reply

To the Editors: We find it difficult to relate the comments in the first part of Dr. Goodlin's letter to our own particular study. Our study was designed to find out whether acid-base status at birth in term infants would be predictive of neurodevelopmental outcome at age 4 to 5 years. The outcome we were concerned with was not primarily cerebral palsy; rather it was the relatively large proportion of children (10% to 20%) with disability caused by subtle neurodevelopmental impairment. As Dr. Goodlin correctly points out, cerebral palsy is a relatively rare condition. Had we wished to study the possible association of acid-base status at birth and cerebral palsy, we would not have chosen a cohort design.

We used as outcome measures a wide range of standardized developmental tests. Dr. Goodlin suggests that results of such tests carry no clinical or medicolegal validity. On the contrary, such tests are widely used in clinical practice on both sides of the Atlantic, and our experience in the United Kingdom is that tests of this type are certainly recognized in courts of law as valid measures of neurodevelopmental status in children. We showed no association whatever between poor performance on these tests and our measure of acid-base status. The "impairment codes" that Dr. Goodlin has singled out were derived from these standardized tests and merely represent one of many attempts to ensure that we were not missing any associations in our data. We believe the conclusions we have drawn are entirely valid within the context of our study and are well supported by our data.

Dr. Goodlin, as expected, raises several pertinent issues on the question of fetal acidosis. In particular, he poses the question as to whether maternal acidosis in labor could have made a significant contribution to the fetal acidosis at birth. If so, this "apparent" fetal acidemia could not be considered physiologic. This is extremely unlikely because of several issues. In our study we were considering severe levels of fetal acidosis: a first level that produced a pH <7.12 and a second level with a pH <7.04 (mean pH for this group was 6.97). At these fetal levels the maternal contribution would be small.[1] In the original study from which our cohort was drawn, simultaneous umbilical arterial and venous measurements were made.[2] The base excess was always greater and the pH lower in the umbilical artery than in the umbilical vein. Hence we assumed the acidosis to be mainly emanating from the fetus. A further study of these paired samples demonstrated that maternal intrapartum factors as opposed to fetoplacental factors made a comparatively small contribution to fetal arterial acidosis.[3]

Hence we do not agree with Dr. Goodlin's suggestion that in the absence of measures of maternal acid-base status our umbilical arterial measures are "futile."

As to the question of the "physiologic" nature of the response, it is the production of lactic acid by the fetoplacental unit as an energy-supplying response to anaerobiosis—the very process referred to by Dr. Goodlin—that we term "physiologic."

The issue of acidosis and its relation to asphyxial injury needs urgent resolution. We believe our study is entirely valid in suggesting that a one-off measure of umbilical arterial pH and base deficit is not a good measure of fetal asphyxia, a view increasingly shared by others.[4-6]

Spontaneous resolution of a nuchal fetal cystic hygroma diagnosed early in the second trimester of pregnancy

To the Editors: We read with interest the article by Bronshtein et al. (Bronshtein M, Rottem S, Yaffe N, Blu-

Fig. 1. Nonseptated nuchal cystic hygroma in 14-week-old fetus. *Arrow* is aimed at cystic mass.

menfeld Z. First-trimester and early second-trimester diagnosis of nuchal cystic hygroma by transvaginal sonography: Diverse prognosis of the septated from the nonseptated lesion. AM J OBSTET GYNECOL 1989; 161:78-82). The authors report on eight cases of cystic hygroma diagnosed early in the second trimester of pregnancy. In the four cases of nonseptated nuchal cysts, normal fetal karyotype was detected in amniocentesis, and in all of them spontaneous resolution of the cystic neck mass was observed on further scans. However, in the septated cystic hygromas the outcome was grave and in two cases an abnormal fetal karyotype was found.

We have recently encountered two cases of nonseptated cystic hygromas (Fig. 1) with spontaneous resolution of the sonographic signs of cystic neck mass on further scans during a few weeks. Both cases were first diagnosed at 14 weeks' gestation. In one of the fetuses genetic amniocentesis performed at 16 weeks of pregnancy revealed a normal 46,XX karyotype, and the pregnancy was allowed to continue, resulting in delivery of a normal healthy infant. However, chromosomal analysis of the second fetus revealed trisomy 18, and the pregnancy was terminated.

Our data of an unfavorable outcome in a nonseptated nuchal hygroma are in disagreement with the author's suggestion and conclusion that both types of hygromas are present: "septated lesion—bad outcome" versus "nonseptated lesion—good outcome." We agree with the authors that more data should be collected to correctly assess the fetal prognosis in cases of early detection of cystic nuchal hygromas.

Israel Meizner, MD, Arie Levy, MD, and Jacob Cohen, MD
Ultrasound Unit, Division of Obstetrics and Gynecology, Soroka Medical Center, P.O. Box 151, Beer Sheva 84101, Israel

Reply

To the Editors: We have read with interest Drs. Meizner, Levy, and Cohen's letter, and we are grateful for their important contribution, which strengthens the recommendation expressed in the last paragraph of our aticle: "Until more data are collected to support the relatively good prognosis of those cases not associated with hydrops, we recommend amniocentesis for karyotyping and α-fetoprotein measurement in each case of cervical cystic hygroma."

Since the publication of our article, our series of septated and nonseptated nuchal cystic hygromas increased significantly, and it now consists of 27 cases—14 nonseptated and 13 septated cystic hygromas. Out of the 13 cases with the septated lesions, six were dyskaryotic fetuses (three trisomy 21, two trisomy 18, and one 45,XO); all of these suffered intrauterine fetal death or therapeutic abortion. Five other pregnancies in this group, whose fetal karyotype is unknown, ended in missed abortion. The last two fetuses in this group of septated hygromas were eukaryotic and were delivered at 29 and 34 weeks, respectively. However, the first of them suffered from hydrocephalus and fetal distress and died in the early neonatal period. The second was delivered at 34 weeks of gestation and developed normally afterward. Out of 13 pregnancies with septated cystic hygromas, only one generated a normal fetus, i.e., a "take-home baby" rate of 6.2%.

In the group of nonseptated cystic hygromas, out of 14 diagnosed cases, 13 were delivered as normal healthy, eukaryotic neonates, whereas the fourteenth suffered nonimmune hydrops and early neonatal death. In this group the "take-home baby" rate was 92.8%, which obviously is a significantly better outcome than that of the septated cystic hygromas.

As to the case of Drs. Meizner, Levy, and Cohen, with cystic hygroma and trisomy 18, we speculate that one may diagnose a septated lesion by looking at their figure. The arrow is indeed aimed at the cystic mass, but the white horizontal delicate line appearing in the cystic hygroma in their figure, may well represent a septum within the cytic lesion. Moreover, this picture seems to be taken from a transvaginal scan performed with a Siemens ultrasonography instrument, using a 5.0 MHz transducer. The resolution of the 5.0 MHz transducer in our experience is somewhat inferior to that of a 6.5 MHz transducer; therefore delicate septae within a cystic hygroma might not be seen with the lower frequency transducer and may be detected with the higher frequency transducer (6.5 MHz). Regardless of such a possibility, we absolutely agree with Drs. Meizner, Levy, and Cohen, that all of us must be very careful and therefore determine the karyotype in every detected cystic hygroma—septated and nonseptated. At the same time we must conclude from our enlarged series the same conclusion we reached in our article: "septated lesion—bad outcome" versus "nonseptated lesion"—relatively "good outcome." The fetal death rate was 92% (12/13) in the "septated" group versus 7% (1/14) in the "nonseptated" group, and the "take-home baby"

rate was 7.7% in the "septated" group versus 93% in the "nonseptated" group.

Again we thank Drs. Meizner, Levy, and Cohen for their important contribution and accept their conclusion that karyotype determination should be recommended in every case of diagnosed cystic hygroma—both the high-risk (septated) and the relatively low-risk (nonseptated) lesion.

Mortality rates ignore population segment

To the Editors: An article by Resnick et al. (Resnick MB, Carter RL, Ariet M, et al. Effect of birth weight, race, and sex on survival of low-birth-weight infants in neonatal intensive care. Am J Obstet Gynecol 1989; 161:184-7.) reports mortality rates among infants cared for in 10 neonatal intensive care units that constitute the State of Florida's Perinatal Intensive Care Program. These babies were born during a 7-year period. The data presented are very useful, but with one very important caveat. The authors failed to address those babies who were never transferred to the program. As a consequence, their mortality figures are applicable only to programs with referral patterns exactly like theirs.

Saigal et al.[1] illustrate the error introduced when babies born in the community but never transferred to the program are ignored. A total of 66 (12%) of 521 babies with birth weights of 500 to 1000 gm died in community hospitals. None cared for only at community hospitals survived. If these 66 babies had been ignored, mortality rates for the group would have fallen from 53% to 46%. For comparison, mortality figures for live born infants from an inborn population that is approximately 65% black and 80% insured by a third party (private insurance, health maintenance organization, or Medicaid) born during the period July 1987 to December 1988 is provided by birth weight and gestational age in Table I. Provision of data by gestational age is less exact than by birth weight, but is inherently more useful to the obstetrician, and perhaps is as accurate with modern obstetric practice as is prenatal estimate of weight.

Table I. Mortality rates by birth weight and gestation

	*No.**	*Survival (%)**
Birth weight (gm)		
<501	9	0.0
501-600	17	5.9
601-700	11	54.5
701-800	16	56.2
801-900	12	100.0
901-1000	14	92.9
Gestational age (wk)		
<23	15	0.0
23	9	11.1
24	11	27.3
25	15	73.3
26	20	80.0
27	10	80.0
28	16	100.0

*Babies born in hospital July 1987 to December 1988; survival to discharge from hospital.

Although the point estimates of survival rates by birth weight are useful, the utility could be enhanced by the 95% confidence limits of survival rates. Variation by year or by hospital could be used to determine the variability in the estimate. The clinician could then more accurately convey the uncertainty of survival in these small infants.

Kenneth L. Harkavy, MD
Division of Neonatology, Columbia Hospital for Women Medical Center, 2425 L St. N.W., Washington, DC 20037

REFERENCE

1. Saigal S, Rosenbaum P, Hattersley B, Milner R. Decreased disability rate among 3-year-old survivors weighing 501 to 1000 grams at birth and born to residents of a geographically defined region from 1981 to 1984 compared with 1977 to 1980. J Pediatr 1989;114:839-46.

Reply

To the Editors: We appreciate the opportunity to respond to the three points raised by Dr. Harkavy in his Letter to the Editors.

In our sample of >16,000 neonates who received neonatal intensive care unit care in Florida's 10 Regional Perinatal Intensive Care Centers, we found no significant differences between survival of inborn neonates and that of neonates transferred from other hospitals. Data from the State of Florida indicate that the vast majority of high-risk infants in the 10 catchment areas were transferred to one of our centers for neonatal intensive care unit care. If the severity of illness in the transferred group differed from that of the inborn group, the survival rates should have been different. They were not.

Whereas gestational age is widely used by obstetricians as an indicator of prematurity, it is quite inexact for infants of extremely low birth weight (<1000 gm). It is hoped that research with ultrasonography in the coming decade will provide a more accurate method to evaluate the degree of prematurity.

When we analyzed our data by both race and sex, the 95% confidence level was a maximum of ±2% for neonates with birth weights of >1000 gm, ±4% for those who weighed 600 to 100 gm, and ±6% for those who weighed <600 gm. A table listing the SE for mortality in each of the 20 birth weight categories by race

and sex (from which the confidence levels were derived) may be obtained from the first author.

How sperm commence movement and their isolation for in vitro fertilization and sex selection

To the Editors: Recent observations have shown that there is no movement in a drop of just-ejaculated semen, reflecting the quiescence of sperm in vivo. Within a few minutes, the terminal filaments of the sperm tails begin to vibrate very rapidly; soon thereafter a wave of undulatory movement passes up the tail toward the midpiece, followed in short time by a vibratory movement of the head, all in situ. By the time the seminal fluid approaches normal viscosity, suddenly the sperm begin very rapid forward locomotion.

If a drop of such semen is placed in a glass slide, converted into a hanging drop for placement on a small gas chamber with inlet and outlet, adapted for microdissecting micropipette on the microscope stage, and carbon dioxide is passed into the chamber about the hanging drop, all sperm movement instantly ceases. Replacement with air restores all movement at once. This was shown originally to be a result of an intrinsic, nontoxic effect of carbon dioxide.[1]

With phase contrast microscopy, which facilitates the visualization of the sperm in the living state, this immobilization enables one to readily aspirate a single sperm from its normal environment for study. As an aid in overcoming infertility in men with marked oligospermia, Lawe-King et al.[2] achieved for the first time unequivocal in vitro fertilization of the mature human oocyte by microinjection of a single sperm via the zona pellucida into the perivitelline space. The immobilization technique cited above might well facilitate the aspiration of the single, capacitated sperm for in vitro fertilization.

To aid the man who is the last male member of a family tree, from the lot of immobilized sperm, a Y chromosome containing gamete could be aspirated for in vitro fertilization. The X and Y sperm are clearly discernable in phase contrast by the size and shape of their respective heads: the Y sperm head in profile is likened to a truncated gothic arch; the X sperm is more wedge-shaped in outline. In face view both are oval, the X is larger. The Y sperm has a longer tail as shown with a map measurer in enlarged photographs of each type. The quinacrine hydrochloride stain showed the smaller-headed sperm to contain the fluorescent spot, indicative of the Y chromosome. The smaller headed, lighter Y sperm with longer tail swims faster than the larger, heavier, shorter tailed X sperm.[3]

Prolongation of pregnancy and survival of second twin

To the Editors: It would appear that some overseas authors are as uninformed of our literature as we are sometimes of theirs. Despite the claim of Feichtinger et al. (Feichtinger W, Breitenecker G, Fröhlich H. Prolongation of pregnancy and survival of twin B after loss of twin A at 21 weeks' gestation. Am J Obstet Gynecol 1989;161:891-3) that placement of a cerclage after the delivery of an immature first twin was a previously unreported unique aggressive approach, this technique has been included in at least 10 case reports in the American literature.[1-3] The longest interval between deliveries of multiple gestations in the American literature has been 99 days,[2] in contrast to the authors' 12 weeks. Unfortunately, maternal deaths caused by sepsis can occur after cerclage.[4] Judging from comments at the Ninth Annual Meeting of the Society of Perinatal Obstetricians, February 2-4, 1989, New Orleans, Louisiana, the authors' procedure has recently been done many times. It is not without its risks.

Robert C. Goodlin, MD

City and County of Denver, Department of Health and Hospitals, 777 Bannock St., Denver, CO 80204-4507

Reply

To the Editors: We thank Dr. Goodlin for his interest in our single case report.

The three references quoted all refer to triplet pregnancies, which may indeed be different from twin pregnancies. The third reference refers to a triplet pregnancy where the infants were delivered on three consecutive days, and it is not at all similar to our case. Obviously, cerclage, particulary in the presence of ruptured membranes, carries significant risks to the mother. However, in the 30 years since reference 4 was published, there have been advances in antibiotic treatment and fetal surveillance.

We would be very interested in corresponding with other obstetricians who have done procedures similar to ours.

Wilfried Feichtinger, MD
Trauttmansdorffgasse 3A, A-1130 Vienna, Austria

Correction

In the article by Tulandi et al., "Treatment-dependent and treatment-independent pregnancy among women with periadnexal adhesions" (AM J OBSTET GYNECOL 1990;162:354-7), on page 355 in the right-hand column of text, line 15 "in the nontreated group (n = 67)..." should have been "(n = 49)..." and line 16 "in the treated group (n = 34)..." should have been "(n = 37)...." On page 356, in Table II under the Intrauterine column of Treated pregnancy, the number 12 should have been 19, the number 3 should have been 4, 60.0% should have been 95.0%, and 15.8% should have been 21.0%. Under the Ectopic column, the number 1 and 5.3% in the bottom row of the table should have been deleted and replaced with —.

For further information please contact: Organizing Secretariat, Fondazione Giovanni Lorenzini, Via Monte Napoleone, 23, 20121 Milan, Italy. Tel.: 02/76.00.22.67 and 78.38.68. Fax: 02/78.15.11.

Reproductive Scientist Training Program. The Reproductive Scientist Training Program is sponsored by the American College of Obstetricians and Gynecologists, the American Fertility Society, the American Gynecological and Obstetrical Society, the Association of Professors of Gynecology and Obstetrics, the Council on Resident Education in Obstetrics and Gynecology, GynoPharma Incorporated, the APGO Medical Education Foundation, the Society for Gynecologic Investigation, and the National Institute of Child Health and Human Development. This training program is designed to facilitate research training of obstetrician-gynecologists in contemporary research approaches and techniques, and to further progress in the reproductive sciences in medical school departments of obstetrics and gynecology. The areas of research interests covered by the program are broadly defined, but the emphasis in this training will be in cell and molecular biology as applied to problems in reproductive endocrinology, genetics, maternal-fetal medicine, oncology, infectious disease, or other aspects of reproduction. Specifically we wish to attract promising physicians in their fourth year of obstetric-gynecologic residency or near completion of a subspecialty fellowship who desire, in addition to their clinical skills, to develop strong basic science research skills and understanding in fields such as cell and molecular endocrinology, genetics, immunology, and oncology as related to reproductive medicine. This program will consist of 2 years of basic research training after completion of a residency in obstetrics and gynecology or subspecialty fellowship. These initial 2 years of laboratory investigation will be followed by a 3-year period in a department of obstetrics and gynecology, during which time the individual will be expected to spend at least 75% time in research, with the balance for clinical activity. Thus the complete program entails a 5-year commitment to basic science research. We wish to attract promising physicians who will have completed an approved 4-year residency program and who desire to spend several years developing strong basic science research skills in addition to their clinical skills, and who are committed to a career in academic obstetrics and gynecology. Women and minorities are encouraged to apply. For more information please write: Executive Director, Association of Professors of Gynecology and Obstetrics, 409 12th St., SW, Washington, DC 20024. Deadline for applications is October 15, 1990; to start July 1, 1991.

Department Chairman Obstetrics/Gynecology

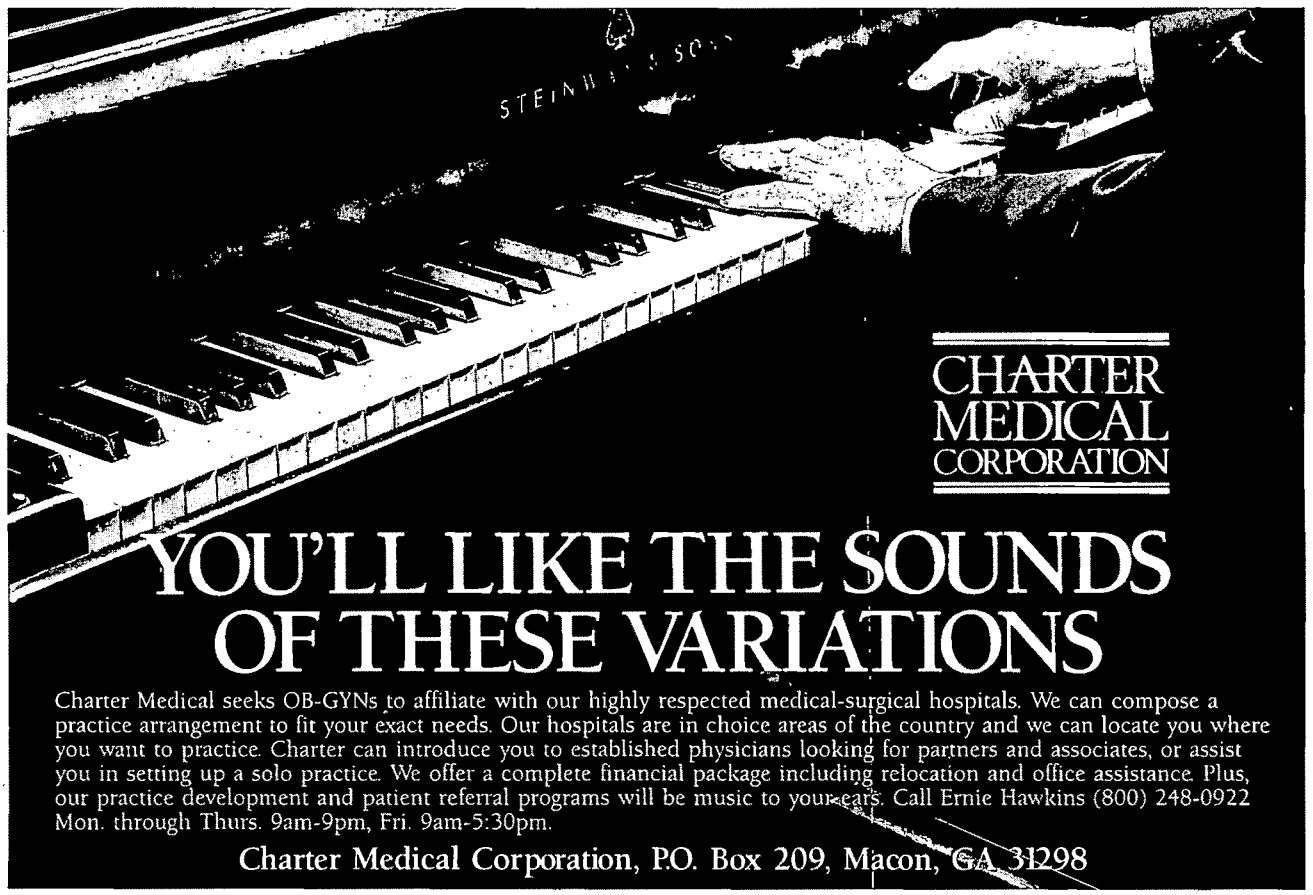
Come Build A Strong And Healthy Department In Southern California.

If you're looking to make a significant impact on the future of health care, look to FHP. We're one of the nation's most progressive and fastest growing HMOs. We're also a recognized innovator in providing high quality patient care. This strong position in the field allows us to offer an outstanding professional opportunity to an exceptional physician, along with the following:

- Tremendous professional autonomy
- Skilled colleagues in every discipline
- Sophisticated health care equipment and systems
- Excellent advancement opportunities

In this critical position, you will supervise a department of 14 physicians providing over 2,500 deliveries per year and a wide range of gynecologic surgery every year. You will provide department direction, management and educational support. We're seeking a board certified physician with a California license, a minimum of 5 years OB/GYN experience and strong academic and leadership skills. Excellent communication and clinical skills and previous management or department chairman experience preferred.

At FHP, you'll work on staff with highly skilled colleagues, including:



- Neonatologists
- Nurse Midwives
- OB/GYN Nurse Practitioners.

You will also have the time to enjoy all of the benefits of our Southern California location. From a wide range of recreational activities to a wealth of cultural options, there's something to fit every lifestyle. In addition, we feature affiliation with the University of California, Irvine, one of Southern California's most respected universities. Here, you'll be able to participate in a rewarding clinical professorship.

FHP offers a compensation package that is commensurate with your experience. Make an important contribution to a dynamic health care leader. For immediate consideration, call **FHP Professional Staffing at (800)336-2255 (in California) or (800)446-2255 (outside California), or send your resume/CV to FHP, Professional Staffing, 9900 Talbert Avenue, Fountain Valley, CA 92708.**

The Baystate Medical Center is the major provider of tertiary care in Western Massachusetts. It has recently expanded its resources through its designation as the Western Campus for Tufts University Medical School. In response, the Department of Obstetrics and Gynecology is expanding its full time faculty group.

The Department has over six thousand deliveries and three thousand operative procedures. Our staff consists of forty-five community based physicians, five certified nurse midwives, and eleven full time faculty in the fields of Maternal-Fetal Medicine, Reproductive Endocrinology, Gynecologic Oncology and Primary Care. The Department has a major commitment to Student Education and has an independent Resident Education Program with twenty residents. Excellent opportunities exist for basic and clinical investigation in many areas.

Baystate Medical Center offers a salary and academic rank commensurate with experience. The Department also has a practice plan. Send Curriculum Vitae or contact:

Laurence E. Lundy, MD, Chairman, Obstetrics and Gynecology
John Powell, MD, Chief, Gynecologic Oncology
Patrick O'Grady, MD, Chief, Maternal Fetal Medicine
Helena Wiczyk, MD, Chief, Reproductive Endocrinology

AA/EOE

CHIEF OF OBSTETRICS AND GYNAECOLOGY

DOCTORS HOSPITAL is currently redeveloping the existing hospital into a new three hundred bed Multicultural Health Care Campus. Phase I of the redevelopment just opened, brings medical offices and new ambulatory programs to the hospital. Phase II of the redevelopment scheduled to open in 1994 replaces the current acute care facility with a two hundred and sixty bed facility.

As Chief of Obstetrics and Gynaecology you will participate in the development of a new and enhanced program to better serve the needs of a diverse multicultural community. You will be supported by strong clinical and professional programs including a new Ambulatory Pre and Post Natal Program.

The ideal candidate will be a team leader committed to a high standard of Obstetrical and Gynaecological care, sensitive to the needs of our patients.

Candidates who have a strong clinical background and are interested in this opportunity should send their curriculum vitae to:

Chairperson, Obstetrics/Gynaecology
Search Committee
The Doctors Hospital
45 Brunswick Avenue
Toronto, Ontario
M5S 2M1

DOCTORS HOSPITAL
Multicultural Community Health Campus

OBSTETRICS/GYNECOLOGY

Here's a practice opportunity we believe you would enjoy. Six family physicians, two surgeons, an optometrist and a clinical psychologist in a busy practice in sister cities on the Red River in southern North Dakota/western Minnesota. The clinic facility is new with ample room for additional staff. Hospital is a modern 95 bed hospital with over 360 deliveries a year. Two of the physicians on staff are currently doing C-sections.

Wahpeton/Breckenridge has a combined population of 15,000 with a patient draw area of over 40,000. Wahpeton is the home of the ND State College of Science and each community has public and parochial primary education.

Will join a 250 physician multispecialty group affiliated with a 400 bed level II hospital which has a NACHRI designated Children's Hospital and a 24 bed level III ICN.

For further information regarding this excellent practice opportunity please contact Robert Ostmo, M.D., 227 6th St. N., Breckenridge, MN 56520 or call 1-218-643-7813.

CHAIR
DEPARTMENT OF OBSTETRICS/ GYNECOLOGY
JAMES H. QUILLEN COLLEGE OF MEDICINE
EAST TENNESSEE STATE UNIVERSITY

Candidates are being sought for the position of Chair of the Department of Obstetrics/Gynecology, James H. Quillen College of Medicine, East Tennessee State University, a community-based medical school which graduated its ninth class in May 1990. The Department currently has 12 full-time faculty, active research programs, an established faculty practice plan which includes the subspecialities of maternal fetal medicine and reproductive endocrinology. It also includes 30 part-time and volunteer faculty in this and neighboring communities. The Department has significant teaching responsibilities in undergraduate, graduate, and continuing medical education. The College of Medicine is located in a prosperous, beautiful Southern Appalachian Mountain community, with a population base of over one million in the immediate referral area. Candidates must be board certified in Obstetrics and Gynecology with proven expertise in teaching, research, and administration. Interested applicants should contact Steven L. Berk, M.D., Chairman, Obstetrics/Gynecology Search Committee, Department of Internal Medicine, P. O. Box 21,160A, Johnson City, Tennessee 37614, (615) 929-6282. ETSU is an AA/EOE.

Postdoctoral Training Program in Medical Genetics

The Interdepartmental Medical Genetics Program at Stanford University School of Medicine provides advanced clinical and/or research training related to human inherited disease. Well-represented areas of the program include:

- The molecular basis of heritable disorders including polygenic and multifactorial diseases.
- Chromosome structure and function.
- Genome and gene mapping.
- The development of methods to manipulate and to study large fragments of DNA.
- Developing animal models and new treatment modalities of human genetic disease by homologous recombination.

Individuals with an MD, PhD, or equivalent degree are eligible for this three-year program which includes an extended period of research training with one of twenty-six training faculty and the opportunity to pursue applied training in clinical genetics, clinical cytogenetics, or molecular genetics in an ABMG-accredited setting. Minority individuals are especially encouraged to apply. For information and application forms, contact:

Uta Francke, M.D.

Send CV To: Joyce Leslie, M.D., Planned Parenthood of Tompkins County, 314 W. State St., Ithaca, NY 14850.

Planned Parenthood®
of Tompkins County

PERINATOLOGIST

Denver, Colorado

Rose Medical Center, Denver, Colorado is seeking a second BE/BC perinatologist to work full-time in a 400-bed private community hospital adjacent to the University of Colorado Health Sciences Center. With 3,600 deliveries per year, and 27 University Residents rotating through the department annually, Rose is the major private teaching affiliate of the University.

Responsibilities include, primary patient care, private consultation, physician, resident, and nursing education, clinical research, and a limited private practice in perinatology. This individual can expect frequent interaction with the Maternal/Fetal Division at the University of Colorado, and will be eligible for an appropriate clinical appointment at the University. All clinical responsibilities will be shared with the current full-time perinatologist at Rose. Additional call coverage is provided by other perinatologists in the Denver metro area.

A competitive salary guarantee is being offered, with excellent fringe benefits including malpractice insurance.

Qualified applicants, individuals completing fellowship in June, 1991, should forward CV's to:

Robert E. Wall, M.D., Chairman
Department of Obstetrics & Gynecology
Rose Medical Center
4567 East Ninth Avenue
Denver, Colorado 80220
Telephone: (303) 320-2077

—A WELL-KEPT SECRET —
The Blue Water Coast

Port Huron Hospital and its medical staff are seeking two board certified/eligible Obstetrician/Gynecologists to join their thriving community. Port Huron Hospital is a full service, 264-bed regional health care facility with 27 post-partum beds, birth centers, a Level II special care nursery and averages 1,600 births annually.

The geography will be appealing to those who are fascinated by large bodies of water. The City of Port Huron, Michigan, is ideally situated on the Canadian border at the southern end of beautiful Lake Huron, just fifty minutes from metropolitan Detroit. The international Blue Water Bridge provides immediate access to the Province of Ontario.

A highly competitive compensation package is being offered including relocation expenses. Interested candidates should reply to:

Michael R. Donaldson
Director, Physician Recruitment
St. John Outpatient Corporation
31510 Gratiot, Suite 300
Roseville, MI 48066
(313) 296-8610

REPRODUCTIVE ENDOCRINOLOGIST

St. Luke's/Roosevelt Hospital Center is one of New York City's largest voluntary hospitals and affiliated with the Columbia University College of Physicians and Surgeons. The Department of Obstetrics and Gynecology seeks a board certified or board eligible sub-specialist to direct the Division of Reproductive Endocrinology. The Department has approved residency and medical student training programs. The Hospital offers an attractive location on West Side of Manhattan. Salary, hospital and university appointments will be commensurate with qualifications and experience. Contact

HOSPITAL CENTER
114th Street and Amsterdam Avenue
New York, NY 10025

An Equal Opportunity Employer M/F.

MATERNAL-FETAL MEDICINE

The Department of Obstetrics and Gynecology at the University of Tennessee Medical Center at Knoxville is currently recruiting one or two additional BC/BE specialists in Maternal-Fetal Medicine.

This is the chance to join a young, growing, dynamic program which encourages active participation in resident and outreach education and offers ample opportunity for basic and clinical research. More than 700 procedures are done monthly in the Department's autonomous Obstetrical Ultrasound and Antenatal Assessment Unit. Constuction of a new Labor and Delivery suite is expected to be completed in January of 1991.

A highly competitive compensation package, coupled with relatively low malpractice insurance, and proximity to many recreational facilities in beautiful East Tennessee makes this an extremely attractive opportunity for the person interested in combining a rewarding academic career and a full family life.

Academic rank is commensurate with qualifications and experience. Interested persons should send C.V. or inquiries to:

Kenneth F. Trofatter, Jr., MD, PhD
Associate Professor and Director

Director Perinatology—Virginia Beach General Hospital. Develop new birthing center/department with already established NICU. Staffed by two neonatologists and 20 active OB/GYNs. This 263-bed full-service community hospital sees 3.5K deliveries per year and is part of a two-hospital network with excess of $150 million annual revenues. On the coast, this comfortable, stimulating community of 1.5 million is supported economically by the nation's largest naval industrial complex and is within easy access to the Washington, D.C. areas and the Carolinas. The position offers an excellent opportunity to develop a first-rate birthing center in Virginia Beach with office space adjoining the hospital. Excellent compensation package plus relocation. Experienced directors/leaders preferred. Contact Steve George, Tyler & Company, 9040 Roswell Road, Suite 550, Atlanta, GA 30350. (404) 641-6416.

Obstetrics/ Gynecology

WISCONSIN: Marshfield Clinic, a multi-specialty group practice with 350 physicians is seeking BE/BC obstetricians/gynecologists to join expanding (40-50 physician) regional centers in Chippewa Falls and Woodruff, Wisconsin. A third OB/GYN is needed for each facility. Chippewa Falls is located 1 1/2 hours from downtown Minneapolis/St. Paul and twenty minutes from a major four year campus of the University of Wisconsin. Known as the "Lakeland Area" (over 1,000 navigable lakes) Woodruff is truly one of the most attractive vacation areas in the upper Midwest and renown for its year-round outdoor recreational activities. Both communities offer exceptional recreational, cultural, and educational opportunities. An emphasis on quality practice and life-style is combined with a total compensation package on reaching membership in excess of $200,000. Starting salary negotiable. Fringe benefit package outstanding; includes self-insured malpractice. No start-up expense. Send C.V. and references to:

David L. Draves

Spectacular!

norethindrone/ethinyl estradiol

ach white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet ontains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg noreth- ıdrone and 0.035 mg ethinyl estradiol. Each green tablet in 28 day regimen contains inert ingredients.

MPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information rovided with the product and therefore should not be used as the basis for prescribing the product. his summary was prepared by deleting from the complete prescribing information certain text, tables nd references. The physician should be thoroughly familiar with the complete prescribing information efore prescribing the product.

NDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

:ONTRAINDICATIONS: Oral contraceptives should not be used in women who currently have the following onditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophle- ıitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected arcinoma of the breast. 5. Carcinoma of the endometrium or other known or suspected estrogen-depen- ent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice vith prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

he use of oral contraceptives is associated with increased risks of several serious conditions including nyocardial infarction, thromboembolism, stroke, hepatic neoplasia, and gallbladder disease, although the sk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The sk of morbidity and mortality increases significantly in the presence of other underlying risk factors such s hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives hould be familiar with the following information relating to these risks. The information contained in this rief summary is principally based on studies carried out in patients who used oral contraceptives with ıgher formulations of estrogens and progestogens than those in common use today. The effect of long erm use of the oral contraceptives with lower formulations of both estrogens and progestogens remains o be determined. Throughout this brief summary epidemiological studies reported are of two types: etrospective or case control studies and prospective or cohort studies. Case control studies provide a ıeasure of the relative risk of a disease, namely a *ratio* of the incidence of a disease among oral contra- eptive users to that among nonusers. The relative risk does not provide information on the actual clinical ıccurrence of a disease. Cohort studies provide a measure of attributable risk, which is the *difference* in he incidence of disease between oral contraceptive users and nonusers. The attributable risk does pro- ide information about the actual occurrence of a disease in the population. For further information, the eader is referred to a text on epidemiological methods. 1. THROMBOEMBOLIC DISORDERS AND OTHER 'ASCULAR PROBLEMS. a. Myocardial Infarction. An increased risk of myocardial infarction has been ssociated with oral contraceptive use. This risk is primarily in smokers or women with other underlying sk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity, and iabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be two o six. The risk is very low under the age of 30. Smoking in combination with oral contraceptive use has een shown to contribute substantially to the incidence of myocardial infarctions in women in their nid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated vith circulatory disease have been shown to increase substantially in smokers, especially in those 35 ears of age and older among women who use oral contraceptives. Oral contraceptives may compound the ffects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In articular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, vhile estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase lood pressure among users (see section 9 in WARNINGS). Similar effects on risk factors have been ssociated with an increased risk of heart disease. Oral contraceptives must be used with caution in vomen with cardiovascular disease risk factors. b. Thromboembolism. An increased risk of thromboem- olic and thrombotic disease associated with the use of oral contraceptives is well established. Case ontrol studies have found the relative risk of users compared to non-users to be 3 for the first episode of uperficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for vomen with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the elative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospital- :ation. The risk of thromboembolic disease associated with oral contraceptives is not related to length of se and disappears after pill use is stopped. A two- to four-fold increase in relative risk of post-operative hromboembolic complications has been reported with the use of oral contraceptives. The relative risk of enous thrombosis in women who have predisposing conditions is twice that of women without such ıedical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and or two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and uring and following prolonged immobilization. Since the immediate postpartum period is also associated vith an increased risk of thromboembolism, oral contraceptives should be started no earlier than four veeks after delivery in women who elect not to breast feed. c. Cerebrovascular diseases. Oral contracep- ves have been shown to increase both the relative and attributable risks of cerebrovascular events hrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), ypertensive women who also smoke. Hypertension was found to be a risk factor for both users and on-users, for both types of strokes, and smoking interacted to increase the risk of stroke. In a large study, he relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for sers with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for non- mokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for mokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hyper- ension. The attributable risk is also greater in older women. d. Dose-related risk of vascular disease from ral contraceptives. A positive association has been observed between the amount of estrogen and rogestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density poproteins (HDL) has been reported with many progestational agents. A decline in serum high density poproteins has been associated with an increased incidence of ischemic heart disease. Because estro- ens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved etween doses of estrogen and progestogen and the activity of the progestogen used in the contraceptive. 'he activity and amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For ny particular estrogen/progestogen combination, the dosage regimen prescribed should be one which ontains the least amount of estrogen and progestogen that is compatible with a low failure rate and the eeds of the individual patient. New acceptors of oral contraceptive agents should be started on prepara- ions containing 0.035 mg or less of estrogen. e. Persistence of risk of vascular disease. There are two tudies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a tudy in the United States, the risk of developing myocardial infarction after discontinuing oral contracep- ves persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or ıore years, but this increased risk was not demonstrated in other age groups. In another study in Great ritain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation f oral contraceptives, although excess risk was very small. However, both studies were performed with ral contraceptive formulations containing 50 micrograms or higher of estrogens. 2. ESTIMATES OF 'ORTALITY FROM CONTRACEPTIVE USE. One study gathered data from a variety of sources which have stimated the mortality rate associated with different methods of contraception at different ages. These stimates include the combined risk of death associated with contraceptive methods plus the risk attribu- able to pregnancy in the event of method failure. Each method of contraception has its specific benefits nd risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke nd 40 and older who do not smoke, mortality associated with all methods of birth control is low and elow that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who se oral contraceptives have a significant increase in mortality higher than those using other methods of irth control. These facts must be weighed in conjunction with failure rates for other methods and the risk ssociated with subsequent pregnancy. 3. CARCINOMA OF THE REPRODUCTIVE ORGANS. Numerous pidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical ancer in women using oral contraceptives. While there are conflicting reports most studies suggest that se of oral contraceptives is not associated with an overall increase in the risk of developing breast cancer. ome studies have reported an increased relative risk of developing breast cancer, particularly at a ounger age. This increased relative risk appears to be related to duration of use. Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. 4. HEPATIC NEOPLA- SIA. Benign hepatic adenomas are associated with oral contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use especially with oral contraceptives of higher dose. Rupture of benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocel- lular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users approaches less than one per million users. 5. OCULAR LESIONS. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immedi- ately. 6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. The majority of recent studies also do not indicate a teratogenic effect, particularly in so far as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued until pregnancy is ruled out. 7. GALLBLADDER DISEASE. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens. 8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. Oral contra- ceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. This effect has been shown to be directly related to estrogen dose. Progestogens increase insulin secre- tion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects prediabetic and diabetic women in particular should be carefully monitored while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see WARNINGS 1a and 1d), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users. 9. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in women taking oral contraceptives, and this increase is more likely in older oral contraceptive users and with extended duration of use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing progestational activity. Women with a history of hypertension or hypertension-related diseases, or renal disease, should be encouraged to use another method of contra- ception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension between former and never users. 10. HEADACHE. The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause. 11. BLEEDING IRREGULARITIES. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, espe- cially during the first three months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent. 12. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contracep- tive failures. **PRECAUTIONS:** 1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medica- tion should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifam- pin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine and liver function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. b. Increased thyroid binding globulin (TBG) lead- ing to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radio-immunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids, however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINO- GENESIS. See WARNINGS section. 10. PREGNANCY. Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS. Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child. **INFORMATION FOR THE PATIENT: See Patient Package Insert. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS section). Thrombophlebitis and venous thrombosis with or without embolism. Arterial thromboembolism. Pulmonary embolism. Myocardial infarction. Cere- bral hemorrhage. Cerebral thrombosis. Hypertension. Gallbladder disease. Hepatic adenomas or benign liver tumors. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea. Vomiting. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Amenorrhea. Temporary infertility after discontinuation of treatment. Edema. Melasma which may persist. Breast changes: tender- ness, enlargement, secretion. Change in weight (increase or decrease). Change in cervical erosion and secretion. Diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome. Cataracts. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. Acne. Changes in libido. Colitis. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea and withdrawal bleeding may occur in females.

Revised 9/89

ORTHO PHARMACEUTICAL CORPORATION

Introductory remarks 273
Jørgen Jespersen, MD, DSc, Sven O. Skouby, MD, DSc, and Cornelis Kluft, PhD
Esbjerg and Copenhagen, Denmark, and Leiden, The Netherlands

Fundamental aspects of the development of cardiovascular disease

An epidemiologic survey of cardiovascular disease in women taking oral contraceptives 274
Margaret Thorogood, BSc, and Martin P. Vessey, MD
Oxford, England

Changes in oral contraceptive use in Britain may be associated with a reduction in the relative risk of myocardial infarction in young women.

Cardiovascular death among women under 40 years of age using low-estrogen oral contraceptives and intrauterine devices in Finland from 1975 to 1984 281
Erkki Hirvonen, MD, and Juhana Idänpään-Heikkilä, MD
Helsinki, Finland

Increased risk of cardiovascular deaths was not observed among low-estrogen oral contraceptive users under the age of 40 years between 1975 and 1984 in Finland.

Past use of oral contraceptives and cardiovascular disease: A meta-analysis in the context of the Nurses' Health Study 285
Meir J. Stampfer, MD, Walter C. Willett, MD, Graham A. Colditz, MB, BS, Frank E. Speizer, MD, and Charles H. Hennekens, MD
Boston, Massachusetts

The large prospective Nurses' Health Study shows no effect of past oral contraceptive use on risk of cardiovascular disease, which is consistent with a meta-analysis of 13 studies.

Impairment of glucose tolerance: Mechanism of action and impact on the cardiovascular system 292

Henning Beck-Nielsen, MD, PhD, Ole Hother Nielsen, MD, Peder Damsbo, MD, Allan Vaag, MD, Åse Handberg, MD, and Jan Erik Henriksen, MD

Odense, Denmark

Insulin resistance induced by steroids may play a pathophysiologic role for the development of coronary heart disease in pill users.

Role of plasma lipoproteins in the pathogenesis of atherosclerotic disease, with special reference to sex hormone effects 296

Matti J. Tikkanen, MD

Helsinki, Finland

This article summarizes the current concepts of plasma lipoproteins in cholesterol transport and their role in atherogenesis.

Disorders of the hemostatic system and the risk of the development of thrombotic and cardiovascular diseases: Limitations of laboratory diagnosis 305

Cornelis Kluft, PhD

Leiden, The Netherlands

Present knowledge on the relationship between disorders of the hemostatic system and cardiovascular disease is summarized. Limitations of diagnosis of hemostatic disorders are discussed, and use of reaction product assays is advocated.

Interrelations between carbohydrates, lipids, and the hemostatic system in relation to the risk of thrombotic and cardiovascular disease 313

Irene Juhan-Vague, MD, PhD, and Phillippe Vague, MD, PhD

Marseille, France

Insulin resistance is a risk factor for atherothrombosis, which could be in part attributed to the increased level of an inhibitor of the fibrinolytic system, plasminogen activator inhibitor.

†Institutional (multiple-reader) subscriptions are available to public and private libraries, schools, hospitals, and clinics; city, county, state, provincial, and national government bureaus and departments; and all commercial and private institutions and organizations.

‡Individual subscriptions and all student-rate subscriptions must be in the names of, billed to, and paid by individuals. All student-rate requests must indicate training status and name of institution.

Subscriptions may begin at any time.

Contents

Pharmacodynamics and pharmacokinetics

Why do we need pharmacokinetic studies? 316
Eigill F. Hvidberg, MD
Copenhagen, Denmark

To appreciate the clinical relevance of pharmacokinetic data for sex steroids, several study approaches are necessary, particularly those generating dose-response curves.

Selected aspects of the pharmacokinetics and metabolism of ethinyl estrogens and their clinical implications 318
Joseph W. Goldzieher, MD
Houston, Texas

The pharmacokinetics of ethinyl estradiol show substantial differences between populations, between persons, and within the same individual at different times, a phenomenon in large part due to the first-pass effect and the enterohepatic circulation to which estrogens are subject.

Pharmacokinetics of gestagens: Some problems 323
K. Fotherby, PhD
London, England

Intra- and intersubject variability, problems in deriving and interpreting the parameters, and lack of correlation with pharmacodynamic responses severely limit the usefulness of pharmacokinetic studies of gestagens.

Protein binding of active ingredients and comparison of serum ethinyl estradiol sex hormone–binding globulin, corticosteroid-binding globulin, and cortisol levels in women using a combination of gestodene/ethinyl estradiol (Femovan) or a combination of desogestrel/ethinyl estradiol (Marvelon) and single-dose ethinyl estradiol bioequivalence from both oral contraceptives 329
Michael Hümpel, PhD, Ulrich Täuber, PhD, Wilhelm Kuhnz, PhD, Michael Pfeffer, PhD, Klaus Brill, Dipl Biol, Renate Heithecker, PhD, Thomas Louton, PhD, Bernd Steinberg, Wolfgang Seifert, PhD, and Barbara Schütt, MD
Berlin, West Germany

Serum ethinyl estradiol, sex hormone–binding globulin, corticosteroid-binding globulin, and cortisol levels were identical in two groups of women using gestodene or desogestrel containing low-dose combination oral contraceptives.

Oral contraceptives and carbohydrate metabolism

Clinical aspects of the relationship between oral contraceptives, abnormalities carbohydrate metabolism, and the development of cardiovascular disease 334
Ulysse J. Gaspard, MD, PhD, and Pierre J. Lefebvre, MD, PhD
Liège, Belgium

Decreased effects of low-dose oral contraceptives on carbohydrate metabolism may partly contribute to reduce the cardiovascular risk in users.

(Contents continued on page 6A)

Contents continued from page 5A

Mechanism of action of oral contraceptives on carbohydrate metabolism at the cellular level 343
Sven O. Skouby, MD, Ole Anderson, MD, Kresten R. Petersen, MD, Lars Mølsted-Pedersen, MD, and Claus Kühl, MD
Copenhagen and Klampenborg, Denmark

Intake of low-dose oral contraceptives does not deteriorate glucose tolerance, but during treatment a hyperinsulinemic response to oral glucose often develops. The mechanism is most probably an increase in peripheral insulin resistance, which may unfavorably influence lipogenesis and lipolysis.

Low-dose oral contraceptives and carbohydrate metabolism 348
Ian F. Godsland, BA, David Crook, PhD, and Victor Wynn, FRCP, FRCPath
London, England

Low-dose combination oral contraceptives induce changes in measures of carbohydrate metabolism that resemble those seen in persons at increased risk of coronary heart disease.

Oral contraceptives and lipoprotein metabolism

Some aspects on the relationship between oral contraceptives, lipid abnormalities, and cardiovascular disease 354
Göran Samsioe, MD, PhD, and Lars-Åke Mattsson, MD, PhD
Göteborg, Sweden

In light of new information on atherogenesis and lipid metabolism, the possible relationship between oral contraceptives and cardiovascular disease was revisited.

Estrogenic effect of gestodene- or desogestrel-containing oral contraceptives on lipoprotein metabolism 358
Jan A. Gevers Leuven, MD, PhD, Marianne C. Dersjant-Roorda, Frans M. Helmerhorst MD, PhD, Rinse de Boer, MD, A. Neymeyer-Leloux, MD, and Louis Havekes, PhD
Leiden and Hertogenborsh, The Netherlands

Estrogenic effect on lipoprotein metabolism was demonstrated in an open-label, randomized, comparative study during 12 cycles in 68 women not previously taking hormonally active compounds.

Time-dependent alterations in lipid metabolism during treatment with low-dose oral contraceptives 363
Herbert Kuhl, PhD, Winfried März, Claudia Jung-Hoffmann, MD, Frauke Heidt, and Werner Gross, MD
Frankfurt am Main, Federal Republic of Germany

The effects of properly composed low-dose oral contraceptives on lipid metabolism reflect a slight preponderance of the estrogen component.

Contents

Effects of three combined oral contraceptive preparations containing desogestrel plus ethinyl estradiol on lipid metabolism in comparison with two levonorgestrel preparations 370

Helenius J. Kloosterboer, PhD, and Hans Rekers, MD

Oss, The Netherlands

Desogestrel-containing combined oral contraceptive preparations induce higher high-density lipoprotein cholesterol and apoliprotein A_1 levels than comparable levonorgestrel-containing preparations and also give lower low-density lipoprotein cholesterol levels.

Metabolic changes during treatment with two different progestogens 374

Hanne Refn, MD, Andreas Kjaer, MD, Anne-Mette Lebech, MD, Birgit Borggaard, MD, Lars Schierup, MD, and Arne Bremmelgaard, MD

Copenhagen, Denmark

Gestodene, compared with levonorgestrel in oral contraceptives, gives a better lipid profile but affects coagulation factors more. The individual variation in the concentration of the two hormones was considerable.

Effects of ethinyl estradiol combined with desogestrel and cyproterone acetate on glucose tolerance and insulin response to an oral glucose load: A one-year randomized, prospective, comparative trial 378

Bernard J. Jandrain, MD, Dominique M. P. Humblet, MD, Christiane B. Jaminet, André J. Scheen, MD, Ulysse J. Gaspard, MD, PhD, and Pierre J. Lefebvre, MD, PhD

Liège, Belgium

After 1 year of use, oral contraceptives containing ethinyl estradiol combined with desogestrel and cyproterone acetate induced slight increase in blood glucose levels, pancreatic insulin secretion, and hepatic insulin metabolism.

Effects of oral contraceptives on carbohydrate and lipid metabolisms in a healthy population: The Telecom Study 382

Dominique Simon, MD, Colette Senan, Philippe Garnier, MD, Michel Saint-Paul, MD, Edith Garat, Nadine Thibult, and Laure Papoz, PhD

Villejuif Cedex, Créteil, Fresnes, and Paris, France

Oral contraceptives induce an increase in insulin-resistance markers (fasting plasma insulin and triglycerides and 2-hour plasma glucose) without consistent differences according to their composition.

The clinical relevance of oral contraceptive pill–induced plasma lipid changes: Facts and fiction 388

Gundolf Hoppe, MD

Metro Manila, Philippines

Oral contraceptive–induced changes in plasma lipids are not of much clinical relevance because of the absence of an oral contraceptive–associated atherosclerotic risk.

(Contents continued on page 8A)

Contents continued from page 7A

Oral contraceptives and hemostatic variables

Clinical aspects of the relationship between oral contraceptives and abnormalities of the hemostatic system: Relation to the development of cardiovascular disease 392
Cecily C. Kelleher, MD
Middlesex, United Kingdom

The estrogen component of oral contraceptives affects coagulation, particularly the variables factor VIIc and fibrinogen, which may partly explain the risk of thromboembolic disease associated with these medications.

Effects of newer oral contraceptives on the inhibition of coagulation and fibrinolysis in relation to dosage and type of steroid 396
Jørgen Jespersen, MD, DSc, Kresten R. Petersen, MD, and Sven O. Skouby, MD, DSc
Esbjerg and Copenhagen, Denmark

In young women newer oral contraceptives containing third-generation progestogens cause only minor changes in the dynamic hemostatic balance.

Studies on the mechanism of action of oral contraceptives with regard to fibrinolytic variables 404
Teake Kooistra, PhD, Piter J. Bosma, MSc, Jørgen Jespersen, MD, PhD, and Cornelis Kluft, PhD
Leiden, The Netherlands, and Esbjerg, Denmark

Evidence is provided that the use of oral contraceptives may decrease the fibrinolytic capacity in plasma; the mechanism of action of oral contraceptives is discussed.

Metabolic changes during the normal menstural cycle: A longitudinal study 414
Anne-Mette Lebech, MD, Andreas Kjaer, MD, and Paul E. Lebech, MD
Copenhagen, Denmark

No changes were found in lipids/lipoproteins during the menstrual cycle; for the investigation on some coagulation parameters, the days of the cycle may be of importance.

Influence of oral contraceptives on coagulation tests in native blood and plasma 417
Friedebert Kunz, MD, Christoph Pechlaner, MD, Marco Tabarelli, MD, Elisabeth Sölder, MD, and Wolf-Dieter Zwierzina, MD
Innsbruck, Austria

Low-dose oral contraceptives reduce clotting time in native platelet-rich plasma and activated partial thromboplastin time.

Hemostasis profile in women taking low-dose oral contraceptives 420
J. L. David, MD, U. J. Gaspard, MD, PhD, D. Gillain, MSc, R. Raskinet, and M. R. Lepot, MD
Liège, Belgium

Low-dose oral contraceptives significantly modify hemostatic parameters and some of their extreme values might be involved in thrombogenesis, among other added risk factors.

Contents

Effects of long-term gestodene-containing oral contraceptive administration on hemostasis 424
Rosanna Abbate, MD, Stefania Pinto, MD, Carlo Rostagno, MD, Vincenzina Bruni, MD, Daniela Rosati, MD, and Guglielmo Mariani, MD
Florence, Italy

Long-term administration of low-dose ethinyl estradiol-gestodene–containing oral contraceptives results in reduction of an initially oral contraceptive–induced increase in coagulation action (fibrinopeptide A levels).

Comparative studies of 30 μg ethinyl estradiol combined with gestodene and desogestrel on blood coagulation, fibrinolysis, and platelets 430
Leisha Daly and John Bonnar, MD, FRCOG
Dublin, Ireland

Combination oral contraceptives containing gestodene and desogestrel induce similar changes in blood coagulation, fibrinolysis, and platelet function.

Enhanced generation and resolution of fibrin in women above the age of 30 years using oral contraceptives low in estrogen 438
Jørgen Gram, MD, DSc, Steffen Munkvad, MD, and Jørgen Jespersen, MD, DSc
Esbjerg, Denmark

In women above the age of 30 years who use oral contraceptives low in estrogen, increased thrombin formation is balanced by a coincidental increase in tissue-type plasminogen activator and an increase in lysis of fibrin, with no affection of light cigarette smoking.

Personal, practical aspects seen from the Family Planning Clinic's point of view

Oral contraceptives in risk groups: Exclusion or monitoring? 443
John Guillebaud, MD

Introductory remarks

Jørgen Jespersen, MD, DSc, Sven O. Skouby, MD, DSc, and Cornelis Kluft, PhD

Esbjerg and Copenhagen, Denmark, and Leiden, The Netherlands

The first European Conference on Sex Steroids and Metabolism, which was sponsored by the International Sex Steroid Foundation, was organized by the South Jutland University Centre, Esbjerg, and took place at the Ribe County Hospital in Esbjerg, Denmark, on May 18-20, 1989.

These proceedings contain contributions to the conference, which formed the scientific platform for a Consensus Meeting on May 21, 1989. The conclusion of this Consensus Meeting was published in the May 1990 issue of the JOURNAL (162:1335-7).

It was not the purpose of the conference to discuss the effectiveness of the formulations in contraception, which, with all pills, is the primary criterion. It was recognized that in developing new formulations, a driving force has been the clinical and metabolic "side effects" of oral contraceptive agents. These metabolic effects in various systems have not been previously discussed in one meeting and in putative coherence. We attempted this by organizing an interdisciplinary conference of active scientists within the areas of epidemiology, blood coagulation and fibrinolysis, vascular disease, lipid and carbohydrate metabolism, and sex steroids. We believed that by breaking down the traditional separation between these research fields, further progress could be stimulated both with respect to the pathogenesis of cardiovascular diseases and the side effects of oral contraceptives.

This initiative was met with enthusiasm, and more than 200 specialists from all over the world attended the conference. We hope that the present proceedings will be of value not only for the participants, but also for those who were unable to attend the conference.

Finally, we acknowledge the educational grants from the pharmaceutical companies, which made the conference and these proceedings possible. We also express our thanks to those who were actively involved and who successfully performed the tasks delegated to them.

An epidemiologic survey of cardiovascular disease in women taking oral contraceptives

Margaret Thorogood, BSc, Research Officer, and
Martin P. Vessey, MD, Professor of Social and Community Medicine
Oxford, England

Earlier epidemiologic studies have indicated an increase in mortality from certain cardiovascular diseases in young women associated with the use of oral contraceptives. However, since these studies were conducted, newer oral contraceptives containing less estrogen and progestogen have been widely adopted. In addition, an increasing majority of oral contraceptive use is by women under the age of 30 years. Early results from a new case-control study suggest the possibility that the risk of myocardial infarction associated with oral contraceptive use is now lower than in the past, although the previously observed small increase in the risk of subarachnoid hemorrhage appears to be unchanged. (AM J OBSTET GYNECOL 1990;163:274-81.)

Key words: Oral contraceptives, cardiovascular disease

Since oral contraception first became available nearly 30 years ago, the complicated question of the relationship between oral contraceptive use and cardiovascular disease has been researched extensively. It is beyond the scope of this brief article to review the entire epidemiologic literature on the subject, and therefore we concentrate specifically on the most serious of the possible cardiovascular side effects of oral contraceptives, that is, fatal disease. We review previous studies and then describe how the use of oral contraceptives has changed in Britain and consider how it might affect the risk of cardiovascular disease. Finally, we describe a new case-control study that we are conducting and discuss some of the preliminary results.

Methods

The two most important research strategies that have been used in the study of the relationship between the pill and cardiovascular disease are case-control and cohort strategies. The design of cohort studies is described in Table I. In a cohort study two groups of persons are identified: one group that is exposed to the agent of interest (in this case oral contraceptives) and a control group that is similar to the exposed group in the area of other risk factors for the disease but not exposed to the agent of interest. The two groups are followed up, and the incidence of the disease under study is noted for each group. The relative risk of the disease among those exposed can then be calculated from the ratio of the rate of the disease in the exposed

Table I. Cohort studies

Start with exposure to the suspected agent
Exposed cohort (e.g., those taking pill)
Control cohort (e.g., those not taking pill)—otherwise similar to exposed cohort
Both cohorts followed over time (usually several years)
Incidence of the disease is noted in both cohorts
Relative risk is ratio of incidence rate in exposed cohort to that in the control cohort
Absolute risk is incidence rate in exposed cohort minus incidence rate in control cohort

Table II. Case-control studies

Start by finding cases of the disease
Controls are people without the disease but otherwise similar to the cases
History of exposure to the suspected agent is obtained for both cases and controls
Relative risk is ratio of exposed to nonexposed cases divided by the corresponding ratio in the controls
Absolute risk cannot be calculated

cohort to that in the control cohort. Thus, for example, if 10,000 women were in each group and six subjects in the exposed group developed the disease compared with three in the nonexposed group, the relative risk would be 2.

The design of case-control studies is described in Table II. In a case-control study, the starting point is the disease of interest. Cases of the disease are collected, and control subjects are chosen who are as similar as possible to the case subjects without being affected by the disease. The history of exposure to the suspected agent is obtained for both cases and controls, and the relative risk can then be calculated by dividing the ratio of exposed to nonexposed cases by the corresponding ratio for the controls. In a case-control study, absolute risk cannot be calculated, although it can be estimated if the cases are drawn from a defined population.

Epidemiologic studies of oral contraceptives and cardiovascular disease

Almost all of the studies of the relationship between fatal cardiovascular disease and the pill have been carried out in the United Kingdom, and this article concentrates on the British studies.

Cardiovascular death is a rare event in young women, and thus it takes a long time for a cohort study to include sufficient numbers of relevant deaths to make any calculations of risk. Therefore except for two long-established cohort studies that will be described later, most of the available evidence on oral contraceptives and cardiovascular disease has come from case-control studies.

Table III provides a summary of all the previous British case-control studies of fatal cardiovascular disease.[1-6] The method used in these studies has been very similar, and members of the Oxford Department of Community Medicine and General Practice have been closely involved in all but one. In all the studies, matched controls have been chosen from living women registered with the same general practice as the case subjects. In most of the studies, information was collected at a face-to-face interview with the general practitioner, conducted by a research physician. One study, however, collected the information by correspondence with the general practitioner.

Table IV. Cohort studies of oral contraception

Royal college of general practitioners study[7]
- Started in 1968
- Subjects: 46,000 married women, half of whom used the pill at recruitment (exposed cohort); the other half did not use the pill (control cohort)
- Data on mortality collected from the National Health Service Central Registry; still in progress

Oxford–FPA study[8]
- Started in 1968
- Subjects: 17,000 married women, approximately 10,000 of whom used the pill (exposed cohort); others used diaphragm or intrauterine device (control cohort)
- Data on mortality collected from National Health Service Central Registery; still in progress

In addition to the case-control studies, important information has been provided by two long-running cohort studies (Table IV).[7,8] These two studies have contributed a vast amount of information about both beneficial and harmful side effects of oral contraceptives; between them, the two studies have already resulted in well over 100 original scientific publications. However, there is an important limitation on the extent to which information from these studies can contribute to the current debate on the cardiovascular effects of oral contraceptives. Recruitment into these studies took place during the late 1960s and early 1970s, and as a result, the pills used by these women mostly contained 50 μg of estrogen. These studies give little information on the newer pills, which have lower doses of estrogen.

The principal findings in the various studies to date are summarized in Table V. The most frequent and consistent finding has been an increased risk of myocardial infarction; these studies have shown a relative risk in oral contraceptive users that ranges between

around 2 to around 4. Findings from studies of stroke have ranged from a relative risk of 1.4 for subarachnoid hemorrhage to a nearly sixfold increase in risk of thrombotic stroke. Only one study has provided a relative risk for fatal pulmonary embolism; that was a high risk of more than 8, but this study was carried out in the mid-1960s when high-dose preparations dominated the market, and the findings may not be relevant in light of the lower dose preparations in use today.

The findings in these studies of fatal cardiovascular disease, along with those in morbidity studies, have indicated a number of other important associations: (1) Absolute risk increases markedly with age. (2) The risk of myocardial infarction at least is increased by the presence of other risk factors, particularly cigarette smoking. (3) The risks are largely confined to women who use oral contraceptives at the time of death. (4) The risks are influenced little by duration of pill use.

In addition to the studies summarized in Table V, there has recently been a new analysis of mortality in the Oxford-FPA study, which has now accumulated 270,000 woman-years of observation (Table VI). Numbers are still too small for definite conclusions to be drawn, but the most striking finding relates to cigarette smoking. Only one of the deaths from ischemic heart disease occurred in a nonsmoker, and more than half of the cases of fatal subarachnoid hemorrhage were also in smokers. There was also a strong preponderance

of oral contraceptive users, although only two women (both of whom had ischemic heart disease) used the pill at the time of death.

Table VII shows the death rates per 100,000 woman-years according to how recently oral contraceptives were used. These rates have been standardized to take into account the effect of age, parity, social class, and cigarette smoking. The numbers are small, but it appears that the increased risk is of similar magnitude, even in those women who stopped using the pill at least 6 years before the fatal event. This is an unusual finding but not unique, and clearly, this is an area in which further research is needed.

Changes in use of oral contraceptives

The results discussed so far relate to the use of oral contraceptives during the 1960s and 1970s. However, since then, major changes have occurred both in the dosage prescribed and in the ages of the women using them.

Table VIII, which, along with Table IX and Figs. 1 to 4, is compiled from data supplied by Medical Data Index, shows how the prevalence of oral contraceptive use has changed in different age groups during the past decade. Use by women below the age of 30 years has increased, whereas use by those over 30 years has decreased, with the result that prescriptions of oral contraceptives for women under 30 years have gained an increasingly dominant role in the market. In 1978, 72% of all prescriptions were for women under 30 years; by 1987 it rose to 80%.

There have also been changes in the dosage of the preparations in use. Table IX shows the percentage distribution of the different types of preparations used during the past 25 years. In the 1960s the market was dominated by high-dose combination pills that contained 70 to 100 μg or more of estrogen. By 1973, partly as a result of early work on the relationship between oral contraceptives and cardiovascular disease, there was a massive switch to preparations containing lower doses of estrogen. This trend has continued, with combined pills containing 30 μg or less of estrogen gaining dominance in the market. More recently the new biphasic and triphasic preparations, which deliver lower

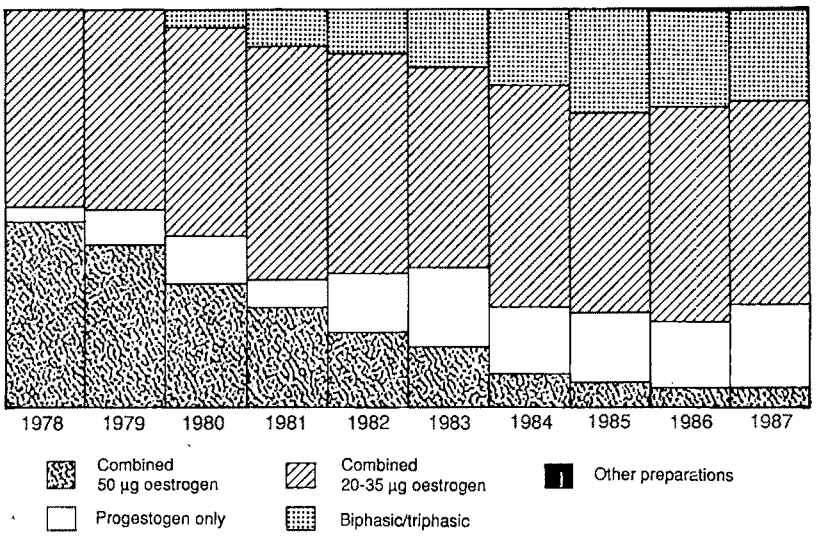

Fig. 2. Percentage distribution of types of oral contraceptives prescribed in women, ages 30 to 39 years.

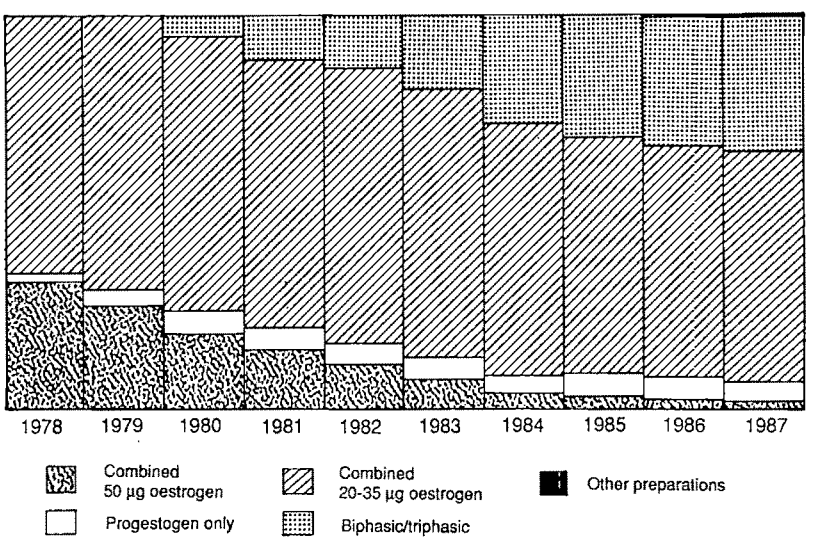

Fig. 3. Percentage distribution of types of oral contraceptives prescribed in women, ages 20 to 29 years.

doses of progestogen over the 28-day cycle, have gained prominence.

Figs. 1 to 4 show how the changes in the dosage of oral contraceptives have affected the age groups differently. In 1978, the older age groups had been much slower to abandon the combined 50 µg pills than younger women, but their use of these preparations declined steadily during the next decade. At the same time, progestogen-only pills, and to a lesser extent for the 30- to 39-year-old age group, biphasic and triphasic pills gained popularity rapidly. In the younger age groups, progestogen-only pills have been used very little, but the biphasic and triphasic pills have shown a remarkably rapid increase in popularity, particularly among the youngest women.

Thus since the major studies on the relationship between oral contraceptives and cardiovascular disease were carried out in the 1960s and 1970s, the pattern of pill use has changed dramatically in ways that might be expected to change the relative risk of cardiovascular disease. Older women, who had the highest absolute risk, use oral contraceptives much less, and those who use them mainly take pills containing either low-dose estrogen or no estrogen at all.

Current case-control study of oral contraceptives

The current case-control study of oral contraceptives and cardiovascular disease began in 1986. All women in England and Wales between 16 and 39 years, who

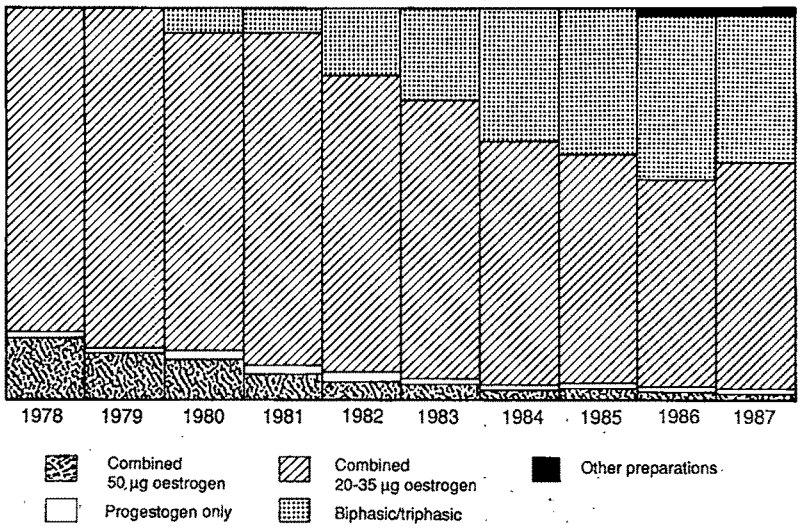

Fig. 4. Percentage distribution of types of oral contraceptives prescribed in women, ages 12 to 19 years.

Table X. Current case-control study of cardiovascular disease in young women: Present position

Total certificates received	934
Investigation continuing	184
Investigation complete	750

died of myocardial infarction, subarachnoid hemorrhage, other stroke, and pulmonary embolism, and/or deep vein thrombosis, have been included in the study.

The design of this study is very similar to that of the case-control studies previously described. The data are collected by medical officers, who carry out interviews with the general practitioners of the cases. There are two control subjects per case, matched by 5-year age group and marital status, and selected from the living women registered with the same general practitioner.

This study is still in progress, and there are 184 patients in whom the investigation is not yet complete (Table X). However, we are in a position to report some very preliminary results of the investigation of the other 750 cases.

Table XI shows the reasons why 231 patients have been excluded from the study. Ten were excluded because they were not residents of England and Wales. We were unable to continue the investigation of another 85 subjects either because the notes were lost, the general practitioner could not be identified, or the general practitioner declined to cooperate. In addition, there were 55 patients in whom we did not feel that there was sufficient medical evidence to ascertain the cause of death. Pregnant patients and those already gravely ill with another disease were also excluded because it was very unlikely that they took oral contraceptives.

Table XI. Current case-control study of cardiovascular disease in young women: Reasons for exclusion of cases

Not resident of England and Wales	10
Medical records mislaid	40
Unable to confirm diagnosis	55
Pregnant or up to 8 wk post partum	49
Case gravely ill with other disease	17
Case institutionalized	22
General practitioner not traced	10
General practitioner refused interview	35

Table XII. Current case-control study of cardiovascular disease in young women: Completed cases by diagnostic group

Myocardial infarction (ICD 410)	130
Subarachnoid hemorrhage (ICD 430)	237
Other strokes (IDC 431-438)	110
Venous thromboembolism (ICD 415.1, 451-453)	42

Patients who were institutionalized were excluded for the same reason.

Thus the results relate to 519 completed cases, but mainly to the 130 patients who died of myocardial infarction and the 237 who died of subarachnoid hemorrhage, since there are not enough deaths in either of the other two categories for conclusions to be drawn as yet (Table XII).

Age distribution by cause of death is shown in Table XIII. There is a strong effect of age on myocardial infarction, a smaller effect for both categories of stroke, and apparently no effect of age on the risk of fatal venous thromboembolism.

The use of female hormones, mainly for contracep-

Table XIII. Current case-control study of cardiovascular disease in young women: Distribution of cases by diagnosis and age group

SAH	8 (3)	22 (9)	38 (16)	56 (24)	113 (48)
OS	4 (4)	14 (13)	14 (13)	27 (25)	51 (46)
VT	8 (19)	10 (24)	5 (12)	8 (19)	11 (26)

MI, Myocardial infarction; *SAH*, subarachnoid hemorrhage; *OS*, other strokes; *VT*, venous thromboembolism.

tive purposes but occasionally for other reasons such as treatment of menorrhagia or endometriosis, was more prevalent among patients with myocardial infarction than among matched controls. Twenty-four percent of the cases used female hormones at the time of death compared with 19% of control subjects, giving a statistically significant relative risk of 1.8. In accordance with the changes in pill dosage and use previously discussed, the relative risk is smaller than that found in most of the earlier studies.

Collecting data about smoking habits from general practice records has in the past been a thankless task. However, there is an increasing awareness among general practitioners of the need to record this information, and in this study it is possible to provide estimates of the relative risk associated with smoking. These data should be interpreted with caution, since it is likely that there is a greater tendency for medical practitioners to record a positive smoking history rather than the absence of a smoking history, and smoking histories were available for a larger percentage of the case subjects than the controls. Nevertheless, the risk of myocardial infarction in women known to be smokers was increased nearly 12-fold (95% confidence intervals, 6 to 23), and it seems reasonable to suppose that there is a real increase in risk of considerable size.

Women already at risk of having a heart attack might well be strongly recommended not to use oral contraceptives or smoke. Inclusion of these women may thus reduce the number of exposed cases and relative risk estimates. About one third of the cases and just 3% of the control subjects had one of the recognized risk factors for myocardial infarction. After cases and controls with recognized risk factors were excluded, the relative risk of both female hormone use and smoking increased. The risk in women who both smoked and used oral contraceptives was increased more than 50-fold.

The risk of subarachnoid hemorrhage in women using oral contraceptives was small. There was a relative risk of 1.4 (95% confidence intervals, 1.0 to 2.0) for women who had ever used female hormones compared with those who had never used them. This risk is similar to that noted in the two previous case-control studies. In addition, there was a risk of subarachnoid hemorrhage associated with cigarette smoking. The relative risk was 3.1 in current smokers compared with women who had never smoked. This compared closely with the relative risk for subarachnoid hemorrhage of 2.9 in current smokers, which was estimated in a recent meta-analysis.[9]

About a fourth of the cases had recognized risk factors for subarachnoid hemorrhage compared with just 3% of the control subjects. However, the exclusion of these women made little difference in relative risk estimates. None of the risk estimates for other forms of stroke or for venous thromboembolism reached statistical significance, but the numbers of cases are small.

In conclusion, changes in the use of oral contraceptives have been described. These changes have led to a considerable reduction in the use of estrogen-containing preparations among women in their thirties. Some very preliminary and incomplete results from a new case-control study still in progress have been described. It does appear that the changes in oral contraceptive use may have had the effect of reducing the relative risk of myocardial infarction for pill users, although there appears to be little change in the (already small) risk of subarachnoid hemorrhage. The most striking finding relates to smoking. Smoking is a major risk factor for both diseases and is a particularly strong risk factor for myocardial infarction. The risk of myocardial infarction in women who both smoke and use oral contraceptives is estimated to be increased more than 50-fold.

We are grateful for the data on oral contraceptive prescriptions in England and Wales, which was kindly supplied by Medical Data Index (Intercontinental Medical Statistics, Ltd.).

Cardiovascular death among women under 40 years of age using low-estrogen oral contraceptives and intrauterine devices in Finland from 1975 to 1984

Erkki Hirvonen, MD,[a] and Juhana Idänpään-Heikkilä, MD[b]
Helsinki, Finland

From 1975 to 1984, there were 1,585,000 women-years of oral contraceptive use and 1,975,000 women-years of copper-bearing intrauterine device use in Finland. During this 10-year period, 20 women between 15 and 39 years of age died of pulmonary embolism, 41 of coronary heart disease, and 311 of intracranial hemorrhage. The diagnoses were confirmed in 89% at necropsy examination. The contraceptive method used by patients was determined in 84% by means of inquiry sent to family planning clinics. Among the 20 patients who died of pulmonary embolism, four died while taking the pill, which gives a relative risk of 1.2 (95% confidence limits, 0.37 to 3.62; $p = 0.78$). The corresponding values for death from myocardial infarction and intracranial hemorrhage were 0.19 (95% confidence limits, 0.05 to 0.70; $p = 0.01$) and 0.36 (95% confidence limits, 0.18 to 0.70; $p = 0.03$), respectively. None among the copper intrauterine device users under the age of 40 years died of pulmonary embolism during 1,383,000 women-years of intrauterine device use. The relative risk of death from intracranial hemorrhage among intrauterine device users was 1.18 (95% confidence limits, 0.70 to 1.99, $p = 0.25$). (Am J Obstet Gynecol 1990;163:281-4.)

Key words: Low-estrogen oral contraceptives, thromboembolism, cerebral vascular complications, coronary heart disease, intrauterine device

In 1970, a new liberal abortion law was passed in Finland, and as a result, the number of legal abortions increased in 3 years to 20/1000 women of fertile age (Fig. 1). After the reorganization of the family planning clinics in 1973, the number of legal abortions in the next 8 years decreased to 12 per 1000 per year. Since the early 1970s, the national policy has been favorable for accepting new contraceptive methods (Table I). Copper intrauterine devices were registered in 1972 and became the most popular contraceptive method in the next 5 years in Finland. It is calculated that these two method are used by 45% to 50% of women who need contraception. Intrauterine devices are recommended mainly to parous women over 30 years of age. Oral contraceptives are contraindicated for women over 40 years, and those over 30 years of age who also smoke are recommended to change to another method. Because the increase in thromboembolism associated with the use of high-estrogen oral contraceptives they were withdrawn from the market 1974.[1] Subsequently, in 1974, the first preparations containing 30 μg of ethinyl estradiol were registered, and according to the sales statistics, their use increased in 10 years up to 82% of oral contraceptive use. Since the cause of death is confirmed in about 90% of cases at necropsy examination in Finland, the diagnostic certainty is high, and it seemed appropriate to study the fatal cardiovascular

Material and methods

Data from the Central Bureau of Statistics were used to count the annual number of women in different age groups and the number of deliveries per year. From 1975 to 1984, the number of women between 15 and 39 years of age has remained constant, between 926,000 and 941,000 in each year (mean, 935,000). The total number of oral contraceptive users and the share of various preparations can be calculated from the national sales statistics. The number of copper intrauterine device users per year can be estimated approximately by using a biostatistical linear model. This requires that the effective lifetime (3 or 5 years), continuation rate during the lifetime, and the number of insertions per year of different copper intrauterine devices are known. During this period, there has been a total of 1,585,000 women-years of oral contraceptive use among all Finnish women and 1,383,000 women-years of intrauterine device use among women under 40 years of age.

Death certificates for women, ages 15 to 39 years, who died of diseases of the circulatory system from 1975 to 1984 were obtained from the Central Bureau of Statistics. The ICD codes (1969 revision of the International Classification of Diseases) and diagnoses and the number of cases are presented in Table II.

Twenty deaths were from pulmonary embolism, 41 from coronary heart disease, and 311 from cerebrovascular diseases. Autopsies were performed in 89% of the cases, and in the rest the diagnoses were based on history, physical signs, neurosurgery, and results of special investigations (computerized tomography, angiography, electrocardiography, spinal fluid, etc.). The case records of those who died in hospitals were obtained, but these were inaccurate to determine the contraceptive method used by the patient. Therefore a request was sent to the residence health centers and family planning clinics. Because of the large number of cerebral arterial complications, only cases from 1980, 1982, and 1984 were included. All inquiries were returned to the Finnish National Board of Health.

In the same period there were 647,000 live births and 40 pregnancy-related deaths (6.18/100,000 births/yr) in Finland. Of these five died of pulmonary embolism (two were complications after cesarean section), one of coronary heart disease, and six of intracranial hemorrhage. The annual number of deliveries and pregnancy-related cardiovascular deaths is subtracted from controls in the statistical analysis (Table III).

The contraceptive method was established in 17 of the 20 patients with pulmonary embolism, in 36 of the 41 cases with coronary heart disease, and in 83 of the 108 patients with intracranial hemorrhage (Table III). Intrauterine devices were found during autopsies. Sta-

tistical significance has been calculated by exact one-sided χ^2 test, and 95% confidence limits for relative risks are test-based calculations.[2]

Results

Among the 20 patients who died of pulmonary embolism, seven women had no predisposing factors for pulmonary embolism; four patients were current oral contraceptive users, but none used an intrauterine device. The contraceptive method could not be determined in three cases. The relative risk of death from pulmonary embolism was 1.2 (95% confidence interval, 0.37 to 3.62; $p = 0.78$) for oral contraceptive users (Table IV).

Among the 41 patients who died of coronary heart disease, the contraceptive method used was established in 36 subjects; only two women were current oral contraceptive users, and five were intrauterine device users. The relative risk of death from myocardial infarction was 0.19 (95% confidence interval, 0.05 to 0.70; $p = 0.01$), for oral contraceptive users and 0.66 for intrauterine device users (95% confidence interval, 0.25 to 1.69; $p = 0.2$).

All 108 patients who died of intracranial vascular disease had intracranial hemorrhage that was caused by a rupture of an aneurysm (60 patients). None had cerebral thromboembolism. Among patients who died of intracranial hemorrhage, the contraceptive method was determined in 84 cases. Nine women were current oral contraceptive users, which gives a relative risk of 0.36 (95% confidence interval, 0.18 to 0.70; $p = 0.03$). Twenty women (23.8%) were intrauterine device users. The relative risk of death from intracranial hemorrhage for intrauterine device users was 1.18 (95% confidence interval, 0.70 to 1.99; $p = 0.25$). Hypertension was present in 18% of patients who died of intracranial hemorrhage, and the mean age in this group was higher (34.6 ± 4.1 years) than that (31.4 ± 6.6 years) in patients with pulmonary embolism.

Comment

The decrease in estrogen content in oral contraceptives resulted in striking decreases in thromboembolic complications in Sweden, but the incidence of the most serious complication, pulmonary embolism, and that of arterial complictions did not decrease.[3] The results obtained in our study suggest that there may be an increased risk of death from pulmonary embolism among low-estrogen (≤50 μg of ethinyl estradiol) users. None of the four oral contraceptive users who died of pul-

monary embolism had any evident predisposing factors for pulmonary embolism as was the case with the three patients whose contraceptive method could not be established. These three patients were not intrauterine device users, but may have used oral contraceptives. It is possible that these four healthy oral contraceptive users might have had some deficiency in the coagulation system, such as low levels of antithrombin III, protein C, or protein S.

The incidence of death from coronary heart disease among oral contraceptive users was very low. This is mainly because coronary heart disease and the presence of its risk factors have greatly influenced the contraceptive choice, decreasing the relative risk of oral contraceptive users.[4]

Cerebral vascular complications are difficult to predict. The mean age of this group was higher than that of women who died of pulmonary embolism. We found hypertension in 18% of patients who died of intracranial hemorrhage, which was caused in 60% by a rupture of an aneurysm. Both hypertension and age influence the contraceptive choice and decrease the relative risk of oral contraceptive users and could increase the risk among intrauterine device users.

An increase in the use of copper intrauterine devices occurred from 1975 to 1979 in Finland, but the number of users remained constant between 1980 and 1984. The continuation rates of different copper intrauterine devices among Finnish women are known and could be used in the calculations of total number of users per year.[5]

The advantage of this study is that the level of diagnostic certainty is high; 89% of the diagnoses were confirmed at necropsy with the remainder made by sophisticated clinical methods. This study includes all deaths from cardiovascular causes during a 10-year period among all Finnish women between 15 and 39 years of age who are potential oral contraceptive users. Bias may be caused by the fact that we were unable to determine with certainty all oral contraceptive users, whereas the use of intrauterine devices was confirmed at necropsy examination. However, there was an excellent correlation between the number of intrauterine devices found at necropsy and that reported by the family planning clinics, which suggests that the reported number of oral contraceptive users is also near correct. Another bias is caused by the fact that the mean age of oral contraceptive users is lower than that of nonusers or intrauterine device users because many physicians prefer to recommend intrauterine devices instead of oral contraceptives for women over 35 years.

These results suggest that modern low-estrogen oral contraceptives are very safe for healthy women under 40 years of age but may still have some influence on the coagulation system, causing an excess risk of one death from pulmonary embolism per 1 million users per year. The risk of death from myocardial infarction seems to be smaller than in control subjects, owing to the careful exclusion of patients with risk factors for coronary heart disease, such as hypertonia, smoking after the age of 30 to 35 years, family history of cardiovascular diseases, and hypercholesterolemia. The proposed protective effect of oral contraceptives against cardiovascular disease could not be confirmed in this study.

The risk of intracranial hemorrhage, which in 60% of patients was caused by a rupture of an aneurysm, does not seem to be associated with the use of the pill, which probably is mainly accounted for by measuring the blood pressure at regular intervals and exclusion of patients with headache from oral contraceptive users. With the modern contraceptive methods, the lowest possible risk is reached through education of medical personnel, liberal use of alternative contraceptive methods, and exclusion of patient with risk factors, for cardiovascular diseases, such as patients with family history and smoking after the age of 35 years from oral contraceptive use.

Past use of oral contraceptives and cardiovascular disease: A meta-analysis in the context of the Nurses' Health Study

Meir J. Stampfer, MD,[a, b] Walter C. Willett, MD,[a, b, c] Graham A. Colditz, MB, BS,[a] Frank E. Speizer, MD,[a] and Charles H. Hennekens, MD[a, d]

Boston, Massachusetts

We examined the effects of past use of oral contraceptives on risks of cardiovascular diseases prospectively in the Nurses' Health Study cohort. The 119,061 participants were 30 to 55 years old and free of coronary disease or stroke in 1976. They provided information on biennial questionnaires and were followed for 8 years. There were 380 nonfatal myocardial infarctions and 105 deaths from coronary disease, 282 strokes, and 48 other cardiovascular deaths. We observed virtually no differences in the rates of various cardiovascular diseases between never and past users of oral contraceptives, regardless of duration of use or time since last use. For major coronary disease, the relative risk was 0.8 (95% confidence intervals, 0.6 to 1.0). A quantitative meta-analysis of 13 studies yielded an estimated relative risk of 1.01 (95% confidence intervals, 0.91 to 1.13) for coronary heart disease. Past use of oral contraceptives has little or no impact on risks of subsequent cardiovascular diseases. (AM J OBSTET GYNECOL 1990;163:285-91.)

Key words: Oral contraceptives, myocardial infarction, cardiovascular disease, stroke, women

The risk of myocardial infarction is increased among current users of oral contraceptives, especially cigarette smokers.[1-14] However, whether this excess risk persists among past users is unclear. Current oral contraceptive use can adversely affect several coronary risk factors, including raising levels of the atherogenic low-density lipoprotein and lower high-density lipoprotein, which is associated with reduced atherosclerosis.[15-17] Oral contraceptives can also impair glucose tolerance[16] and raise blood pressure.[18-21] Despite these deleterious changes in risk factors, most, but not all, studies have failed to observe an increase in risk of cardiovascular disease among women who have stopped using oral contraceptives.[1-5, 12, 22-26] One large case-control study has been widely interpreted as showing an increased risk of myocardial infarction among past users; the magnitude appeared to increase with a longer duration of use.[10] Even a modest excess risk among past users could be important because those women will be older than current users and thus have higher absolute rates of cardiovascular disease. If past use increased this rate by even a small amount, the absolute excess risk attributable to oral contraceptives could be large.

In this article we review the pertinent literature, provide additional information from the Nurses' Health Study, the largest prospective investigation to date of the effect of past use of oral contraceptives on risk of cardiovascular diseases,[24] and perform a quantitative meta-analysis on all available data on this question. We conclude that past use of oral contraceptives is not associated with an excess risk of cardiovascular events.

Methods

The Nurses' Health Study cohort was established in 1976 when 121,700 female nurses 30 to 55 years of age completed a mailed questionnaire that included items on known or suspected risk factors for cancer[27] and coronary heart disease.[28] Follow-up questionnaires are mailed every 2 years to update information on risk factors and to identify newly diagnosed illnesses. The 1976 questionnaire included a complete history of all intervals of oral contraceptive use, and this information was brought up to date by follow-up questionnaires sent in 1978, 1980, and 1982. We defined current oral contraceptive use as use within 1 month of the date of return of the questionnaire. Past use was defined as use that ceased at least 1 month before the return of the questionnaire. Total duration of use was calculated by adding together the durations of all intervals of use for each woman. We also determined the duration since last use of oral contraceptives.

The participating nurses who reported a nonfatal myocardial infarction or stroke were asked for permission to review the medical records. We applied the

World Health Organization criteria for diagnosis of myocardial infarction; these require symptoms plus either enzyme elevations or diagnostic electrocardiographic changes.[29] We used the criteria of the National Survey of Stroke[30] to confirm the diagnosis of stroke. Reported new strokes that required hospitalization and for which additional confirmatory information was obtained (typically from an interview), but for which no medical records were available, were considered probable.

Fatal cases were identified through reports by next of kin and by a systematic search of the National Death Index.[31] Whenever possible, we reviewed the relevant medical records. The category of death caused by coronary disease included fatal myocardial infarctions (confirmed by records or autopsy), or when coronary disease was listed as the underlying cause of death on the death certificate without another plausible cause, and the woman was known to have had coronary disease before her death. In no case did we rely solely on the cause given on the death certificate to confirm a fatal coronary event. Deaths caused by stroke were confirmed on the basis of medical records, autopsy, or death certificate.

The category of fatal cardiovascular disease included fatal coronary heart disease and stroke, as well as sudden death and deaths for which coronary disease was listed as the cause and no more plausible cause could be assigned but for which confirmation was lacking; these latter categories were designated presumed coronary deaths. The category of major cardiovascular disease included fatal cardiovascular disease and nonfatal myocardial infarction and stroke.

This analysis was based on 119,061 women who were free of diagnosed coronary disease in 1976 and who provided information on oral contraceptive use on the baseline questionnaire. Person-time was allocated according to the 1976 exposure variables and updated on subsequent follow-up questionnaires, until death or a nonfatal endpoint was reached, or until the end of the follow-up period, May 31, 1984. We calculated relative risks, which were defined as the ratio of the incidence of cardiovascular end points among past oral contraceptive users compared with never users. Age-specific and age-adjusted rates were calculated using 5-year age categories, and 95% confidence intervals were calculated.[32] We used the Mantel test to evaluate linear trend[32] and proportional hazards models[33] to simultaneously adjust for multiple risk factors. Further details of the methods have been published elsewhere.[24]

Through computer searches and a detailed review of references from the literature, we identified 13 studies with quantitative data on the effect of past use of oral contraceptives on risk of coronary disease. To obtain a quantitative overview of results from different studies, we calculated a weighted average of the estimated relative risks associated with past use of oral contraceptives. Each study's relative risk was given a weight that corresponded to its precision (i.e., the inverse of an estimate of the variance). An estimate of the variance was derived by calculating the standard error from the confidence interval from each study. Thus larger studies (with more precise estimates, i.e., narrower confidence limits) were given greater weight than smaller ones.[34] For studies in which no point estimate or confidence intervals were given, we calculated these from data published in the papers. We made no attempt to weight studies by the estimated quality of information based on study design, potential bias, or other factors.

A separate meta-analysis included only the cohort studies. Five of the 13 studies provided estimates that were adjusted for confounding factors. We estimated the effect of unadjusted confounding in the remaining studies by taking a weighted average (weighted by the inverse of the variance of each study) of the ratio of the adjusted and unadjusted point estimates, and applied it to studies that provided only age-adjusted results. This permitted a meta-analysis that attempted to take into account the effects of confounding variables, so far as this is possible in nonrandomized studies. These meta-analyses make the assumption that each of the studies was estimating the same underlying parameter. Also, the adjustment for confounding makes the assumption that the distribution of confounders was the same in all studies. We recognize that these assumptions are not strictly met, because the studies were conducted in different populations. Despite these and other limitations in the meta-analysis of observational data,[34] this approach can provide a guide about the strength of the evidence, especially since individual studies are so consistent.

Results

Nurses' Health Study. In 1976, 49,269 women were past users of oral contraceptives, 62,718 participants had never used them, and 7074 were current users. During follow-up, nearly all current users in 1976 had become past users. Because use of oral contraceptives became widespread only in the mid-1960s, many of the participants were beyond the age at which their use was usually initiated. Thus never users tended to be older than past users; current users tended to be younger than past users (Table I). In addition, past users tended to be less obese, had more hypertension, and tended to smoke more than never users.

Follow-up of the cohort for fatal outcomes was more than 98% complete; for nonfatal events, the follow-up was 92% complete. In all, there were 380 documented nonfatal myocardial infarctions, 282 strokes (77 fatal

CVD, Cardiovascular disease; *RR*, relative risk; *CI*, confidence interval; *OC*, oral contraceptive.

*Major cardiovascular disease includes fatal and nonfatal stroke, deaths from coronary heart disease, and nonfatal myocardial infarction.

and 205 nonfatal), and 105 deaths from coronary heart disease. In addition, there were 24 sudden deaths and 24 presumed coronary deaths, for a total of 230 cardiovascular deaths.

There was inadequate information to evaluate the risks associated with current oral contraceptive use in detail. However, the risk of major coronary disease (nonfatal myocardial infarction and fatal coronary disease) was significantly elevated in current users; the age-adjusted relative risk was 2.5 (95% confidence interval, 1.3 to 4.9). Seven of the 10 cases occurred among current cigarette smokers.

Because of the differences in age distribution between past and never users of oral contraceptives, all the relative risks are age adjusted. Within each 5-year age category, we observed no evidence of any increase in risk among past oral contraceptive users (Table II). Similar findings were observed in age-specific analyses for each of the various categories of cardiovascular disease.

The age-adjusted results were similar: we found no overall increase in the risk of cardiovascular disease among past users of oral contraceptives (Table III). For all major cardiovascular disease combined, the age-adjusted relative risk was 0.95 (0.81 to 1.11). For major coronary disease it was 0.91 (95% confidence interval, 0.74 to 1.12), and for fatal cardiovascular disease, 0.98 (95% confidence interval, 0.73 to 1.32). When we adjusted for other risk factors using proportional hazards models, the multivariate relative risks decreased slightly (Table III).

Table III also shows the risk estimates by duration of past oral contraceptive use. There was no evidence of a trend toward an increase in risk with an increase in duration of use. Similarly, there was no evidence of a trend in change in risk with increasing duration since last use.[24] The risk was near the null value even for women who recently stopped using oral contraceptives.

Slone et al.[10] observed that premenopausal women, ages 40 to 49, had an age-adjusted and risk factor–adjusted relative risk of 1.6 (95% confidence interval, 1.1 to 2.5) for 5 to 9 years of prior use and 2.5 (95% confidence interval, 1.5 to 4.1) for 10 or more years of use. We specifically examined this group and found no evidence to suggest an increase in risk. Among premenopausal women, ages 40 to 49 years, with 5 to 10 years of prior use, the relative risk for major coronary disease was 0.6 (95% confidence interval, 0.2 to 1.4) and for women with more than 10 years of prior use, it was 0.5 (95% confidence interval, 0.1 to 2.1).

Meta-Analysis of past use of oral contraceptives and cardiovascular disease. Reports from most but not all studies of past use of oral contraceptives and risk of coronary disease have also indicated no increase in risk. The positive findings of Slone et al. were limited to a specific subgroup; no excess risk was found in postmenopausal former users or among past users under age 40 years (Table IV). Overall, after adjustment for

a variety of coronary risk factors, no increase in the risk of myocardial infarction among past users was observed: the relative risk was 1.1 (95% confidence interval, 0.9 to 1.4).

These essentially null findings are consistent with nearly all previous studies addressing this issue (Table V). Preliminary reports[12] from studies listed in Table V have not been included if the data are subsumed in subsequent reports to avoid duplicate counting of the same data. Data from the Oxford Family Planning Study[35] are not included because age-adjusted data, specifically for past users, were not given. In that study past users appeared to have a slight, nonsignificantly elevated risk, but there were only 13 exposed cases, so it is unlikely that their inclusion would have materially influenced the meta-analysis. Of the 13 studies summarized in Table V, none show a significant increase in risk, and all but one report estimates close to the null value. Only one, the study by Jick et al.,[36] has a substantially (although not significantly) elevated point estimate above 1.0. This study had only four exposed cases and only two unexposed cases to serve as the reference category. Moreover, only 15% of the potential patients were enrolled, suggesting the likely occurrence of selection bias.

Most of the studies did not adjust for other coronary risk factors. In general, past users appeared to have a slightly higher baseline risk than did never users. Thus multivariate adjustment tended to slightly reduce the relative risk associated with past use of oral contraceptives. Table V shows that in four of the five studies that calculated both age-adjusted and multivariate relative risks, the adjustment for other risk factors further attenuated the relative risk.

The findings are remarkably consistent in showing little or no effect of past use of oral contraceptives on risk of myocardial infarction. The meta-analysis of all 13 studies, which used both adjusted (where available)

and unadjusted results, yielded a relative risk of 1.05 (95% confidence interval, 0.94 to 1.17) (Table V). A meta-analysis limited to the three cohort studies,[23-25] in which bias may be expected to be minimized, revealed an estimate of 0.85 (95% confidence interval, 0.69 to 1.05). As previously noted, the meta-analysis of all 13 studies probably provides a slight overestimate of the true effect because only a few studies adjusted for confounding factors. In the five studies that did so, the estimate of effect was attenuated by a weighted average of 12%. We applied this estimated effect of uncontrolled confounding to the results of all studies that provided only age-adjusted relative risks according to the method suggested by Greenland.[34] The estimate from this meta-analysis, a relative risk of 1.01 (95% confidence interval, 0.91 to 1.13), probably provides the best guide to the true effect based on the published data. The estimated relative risk of 1.01 lies within the 95% confidence intervals of each of the age-adjusted estimates for the individual studies. The upper bound of 1.13 effectively excludes all but the most modest adverse effect.

Comment

The lack of trend with increased duration of past use, the apparent immediate decline in risk to baseline values after cessation of oral contraceptive use, and the lack of any duration effect in the excess risk associated with current use[11] point to a short-term mechanism rather than a more long-term effect, such as progression of atherosclerosis, to explain the increase in risk of myocardial infarction among current users. Ample biologic plausibility supports this conclusion. Oral contraceptives are known to have an adverse impact on coagulation, presumably through decreasing levels of antithrombin III and increasing levels of several clotting factors.[11, 37]

This conclusion is further reinforced by angiographic and anatomic studies of young women with myocardial infarction. Engel[38] found that oral contraceptive users appeared more likely to have a myocardial infarction without severe diffuse atherosclerosis than did nonusers. In a series of 76 angiograms among women 50 years of age or younger with a prior myocardial infarction, 27 of the 34 patients without serious coronary disease were current oral contraceptive users compared with 15 oral contraceptive users among 42 patients with coronary disease ($p < 0.001$). Of the 18 patients with myocardial infarction without any stenosis of 50% or more, 15 were oral contraceptive users ($p = 0.01$). Similar findings have been observed in smaller series of cases studied by angiography or at autopsy.[38, 39] In animal studies, monkeys eating a typical North American (atherogenic) diet who were given oral contraceptives had slightly less atherosclerosis than did those on the same diet that were given placebo.[40]

Data on the effect of past use of oral contraceptive on stroke risk are too sparse for a formal meta-analysis, and the findings have been inconsistent. The Collaborative Group Study of Stroke in Young Women[41] found a ninefold excess risk of thrombotic stroke and a twofold risk of hemorrhagic stroke in current users, but "there were no important differences between the

percentages of cases and controls who used oral contraceptives at any time," strongly suggesting no effect for past use; no actual data are provided. In contrast to those results and the findings from the Nurses' Health Study, the Walnut Creek Study[42] found a relative risk of 5.3 (95% confidence interval, 1.3 to 22.0) for subarachnoid hemorrhage in past oral contraceptive users, but there was only one case in the never use category (yielding a statistically unstable estimate), and five of the seven cases in past users were smokers and therefore at higher risk.[43] The Royal College of General Practitioners Study[12] found that past users had a relative risk of stroke of 3.6 (95% confidence interval, 1.5 to 8.5), and for subarachnoid hemorrhage specifically, 4.5 (95% confidence interval, 1.2 to 16.5) higher risks than they observed for current uesrs. More than two thirds of patients with subarachnoid hemorrhage smoked, so it is difficult to disentangle the effects of smoking and oral contraceptives. The Oxford Family Planning Study[44] also found a (nonsignificant) increase in risk of subarachnoid hemorrhage in past oral contraceptive users but with only three cases in the never use category.

The hormone dosages used in oral contaceptives has decreased markedly. Most of the oral contraceptive use among past users in the Nurses' Health Study and in other studies reviewed here took place when the dosages were relatively high compared with current practice. Although inconclusive, preliminary evidence suggest that the newer formulations carry a lower risk of myocardial infarction among current users than did the earlier preparations.[26, 35, 45-47] Thus it is likely that the newer preparations also will not carry a residual risk among past users. Collectively, the data from the Nurses' Health Study and the overview of the literature provide reassuring evidence that the risk of coronary heart disease among past users of oral contraceptives is approximately the same as for women who have never used them.

We gratefully acknowledge the Nurses' Health Study participants for their continuing outstanding level of cooperation and the expert help of Stephanie Bechtel, Karen Corsano, Meryl Dannenberg, David Dysert, Barbara Egan, Marion McPhee, Mark Shneyder, and Donna Vincent.

Impairment of glucose tolerance: Mechanism of action and impact on the cardiovascular system

Henning Beck-Nielsen, MD, PhD, Ole Hother Nielsen, MD, Peder Damsbo, MD, Allan Vaag, MD, Åse Handberg, MD, and Jan Erik Henriksen, MD
Odense, Denmark

Macrovascular diseases, especially coronary heart diseases, have been found to be linked to glucose intolerance. Insulin resistance in respect to glucose uptake in peripheral tissues seems to play an important role in the development of glucose intolerance, since subjects with coronary heart disease mainly are hyperinsulinemic. Insulin resistance may induce not only glucose intolerance but also hypertension, obesity, and dyslipoproteinemia (high very low–density lipoprotein and low high-density lipoprotein values), all variables that add to the risk of coronary heart disease. On the basis of these findings, a new syndrome has been postulated—syndrome X. This syndrome may be caused by inherited insulin resistance in skeletal muscles, and secondary to that arterial hypertension, obesity, and dyslipoproteinemia may develop. Insulin resistance in noninsulin-dependent diabetic persons and in hypertensive subjects is located in skeletal muscles, where insulin's ability to promote nonoxidative glucose metabolism is reduced. The key enzyme in this pathway, glycogen synthase, is proposed as the causal defect responsible for the insulin resistance state, at least in noninsulin-dependent diabetic patients. The pill (sex steroids) may induce a clinical situation that is similar to syndrome X. However, it is important to emphasize that many more studies are needed to substantiate these hypothetical mechanisms behind coronary heart disease. (Am J Obstet Gynecol 1990;163:292-5.)

Key words: Insulin resistance, glucose intolerance, coronary heart disease, sex steroids

Sex steroids (the pill) have been found to induce impaired glucose tolerance in a great many pill users.[1] Furthermore, an increased risk of hypertension, dyslipoproteinemia, increased body weight, and coronary heart disease has been reported.[1]

Therefore the question is, how may these events be linked together? Is there a common pathogenetic cause that may link these complications to the pill?

Recent investigations[2] have outlined that insulin resistance in respect to glucose disposal could be the underlying defect. Therefore the importance of insulin resistance in the development of glucose intolerance, arterial hypertension, dyslipoproteinemia, and coronary heart disease will be discussed in further detail in this short article. The cellular abnormalities responsible for peripheral insulin resistance will be considered.

Glucose intolerance

Glucose tolerance, as estimated by the oral glucose tolerance test, depends on several factors, but the most important are insulin secretion and insulin action. A close correlation has been found between these two variables in normal subjects, where they seem to compensate for each other. The result is that glucose tolerance is kept normal even if one of the variables is altered.[3] Thus in most subjects suffering from insulin resistance, it may be compensated by hypersecretion of insulin. Therefore these subjects will develop hyperinsulinemia both in the fasting state and after a meal. If β-cells are unable to produce enough insulin to overcome the insulin resistance, frank diabetes mellitus will result. Therefore insulin resistance may be present in a compensated form, for example, obesity, and an uncompensated form, such as noninsulin-dependent diabetes mellitus. In between normal glucose tolerance and frank diabetes (fasting hyperglycemia), a clinical state characterized by partial compensation of insulin resistance has been defined—impaired glucose tolerance—a clinical state with normal fasting plasma glucose values but postprandial hyperglycemia.

Glucose intolerance, both diabetes mellitus and impaired glucose tolerance, has been linked to macrovascular diseases, especially coronary heart disease.[4] Furthermore, glucose intolerance seems to be a common feature in subjects with arterial hypertension. In a recent article about 40% of hypertensive patients were glucose intolerant.[5] Also, dyslipoproteinemic subjects have been found to be more glucose intolerant than control subjects.[2] Thus taken together, glucose intolerance seems to be a common characteristic of subjects

with dyslipoproteinemia, arterial hypertension, and obesity.

Because insulin resistance is the major underlying defect of glucose intolerance in the subjects described above, the following question may be raised: how does insulin resistance lead to hypertension, obesity, and dyslipoproteinemia?

Role of insulin resistance in the pathogenesis of arterial hypertension

In a recent population study of around 2500 subjects with arterial hypertension, about 40% suffered from glucose intolerance.[5] As many as 85% were either glucose intolerant or obese. Hyperinsulinemia was more frequent in hypertensive subjects than in normotensives, and hypertension was independently associated with hyperinsulinemia. (It means independent of body weight and glucose levels.) Insulin action was not measured in this study, but the high insulin levels indicate that hypertensive subjects were insulin resistant. In fact that conclusion has been supported by measuring peripheral insulin action by means of the euglycemic hyperinsulinemic clamp technique in lean subjects with arterial hypertension.[6] Thus the conclusion that insulin resistance may be of pathogenetic importance for the development of hypertension is based on solid ground, but more studies are needed for further clarification.

How can insulin resistance lead to arterial hypertension?

There are basically three explanations, which more or less are based on the fact that insulin resistance leads to hyperinsulinemia. In other words, compensation for insulin resistance may lead to hyperinsulinemia and hypertension.

Insulin has been found to play an important role in the regulation of sodium reabsorption in the distal tubules.[7] High insulin levels increase sodium reabsorption in a dose-dependent manner. Together with sodium, water is reabsorbed, and the result in an increase in exchangeable water as recently shown in diabetic patients with hypertension.[8] The mechanism for the development of hypertension seems especially to take place in glucose-intolerant subjects who have hyperinsulinemia. The mechanism may be an activation of sodium-potassium–adenosine triphosphatase activity in the distal tubules.[7]

It has also been claimed that hyperinsulinemia may increase the noradrenalin concentration in plasma and thereby the sympathetic tone. That mechanism could explain at least in part the arterial hypertension in insulin-resistant subjects.[8] However, only very high insulin concentrations (unphysiologic values) were able to increase noradrenalin concentrations and only about 50% compared with basal level. In that respect it is important to emphasize that noradrenalin values rises about 2.5-fold by upright posture. Therefore an increase in noradrenalin concentration as a result of hyperinsulinemia may play a minor role in the development of hypertension in insulin-resistant subjects.

The third explanation is based on the fact that intracellular sodium content has been shown to be increased in erythrocytes from hypertensive subjects.[5] This phenomenon may be explained by reduced activity of sodium-potassium–adenosine triphosphatase in the erythrocyte membrane secondary to cellular insulin resistance. If these abnormalities also take place in smooth muscle cells, it may result in narrowing of the lumen of small arteries and thereby explain the peripheral resistance demonstrated in hypertensive subjects. More studies are needed to prove this hypothesis.

Further evidence of the relationship between insulin resistance and arterial hypertension has been outlined recently when rats fed sucrose developed not only insulin resistance but also hypertension.[2] Thus in conclusion much evidence is in favor of the hypothesis that arterial hypertension–like glucose intolerance may be secondary to reduced insulin-mediated glucose uptake in peripheral tissues (muscles). Arterial hypertension may develop as a consequence of compensated insulin resistance but may also be from insulin resistance itself.

Role of insulin resistance in the development of obesity

Insulin resistance in respect to glucose disposal may develop because of environmental factors, such as hyperalimentation and reduced physical activity, but may also be of genetic origin.[10] In genetically obese rats, insulin resistance is located in muscle cells and not in fat cells.[11] This means that compensation for the reduced disposal of glucose in skeletal muscles by hyperinsulinemia may increase triglyceride synthesis in adipocytes and therefore lead to overweight. Hyperinsulinism may also stimulate the appetite and thereby add to the development of obesity. This mechanism for the development of obesity may take place in some subjects, whereas overeating may be the primary abnormality in others. In all obese persons, however, insulin resistance is an important clinical feature.

Role of insulin resistance in the development of dyslipoproteinemia

Subjects with abnormal glucose tolerance are characterized by high triglyceride values (very low–density lipoprotein) and low high-density lipoprotein cholesterol values.[2] Similar abnormalities has been described in subjects with hypertension.[2] Hypertriglyceridemia seems to be secondary to insulin resistance and hyper-

insulinemia. Highly significant correlations have been demonstrated between reduced insulin-mediated glucose disposal and very low–density lipoprotein values.[2] Furthermore, an increase in very low–density lipoprotein synthesis in the liver and a reduction in peripheral clearance of very low–density lipoprotein has been found in hyperinsulinemic insulin-resistant subjects.[2] Thus considerable evidence supports the hypothesis that hypertriglyceridemia is secondary to insulin resistance and hyperinsulinemia is present. Furthermore, reduced high-density lipoprotein cholesterol values seem to be linked to high very low–density lipoprotein values.

Role of insulin resistance in coronary heart disease

Resistance to insulin-mediated glucose disposal is associated very often with hyperinsulinemia, glucose intolerance, increased very low–density lipoprotein, and reduced high-density lipoprotein values and hypertension, all important variables for the development of arteriosclerosis and coronary heart disease.

That cluster of risk factors linked together has lead several researchers to propose a new syndrome, syndrome X, which is defined as follows: (1) resistance to insulin-mediated glucose disposal, (2) glucose intolerance, (3) hyperinsulinemia, (4) increased very low–density lipoprotein triglycerides, (5) decreased high-density lipoprotein cholesterol, (6) hypertension, and (7) increased fat mass. The inherited defect may be insulin resistance in skeletal muscles, whereas all other abnormalities may be secondary.

What is the cellular defect(s) responsible for insulin resistance in subjects with syndrome X?

Until now no studies dealing with that question have been carried out in subjects with well-defined syndrome X. Most investigations, however, have been carried out in glucose-intolerant subjects, that is, diabetic persons with or without the other characteristics of syndrome X. However, in vivo studies of insulin action in hypertensive subjects have also been published.[6] Hypertensive subjects suffer from insulin resistance only in peripheral tissues, whereas the liver seems to react adequately to insulin.[6] In obese subjects with noninsulin-dependent diabetes mellitus, liver, adipose tissue, and skeletal muscles are insulin resistant.[12] However, insulin resistance in skeletal muscles seems to play the quantitatively most important role and also seems to be primary to the defects in the other tissues.[12] Thus based on these facts, it seems meaningful to hypothesize that insulin resistance in skeletal muscles may be the primary defect and a genetic defect in subjects with syndrome X. However, further studies are needed to substantiate this hypothesis.

In skeletal muscles from both hypertensive subjects[6] and those with noninsulin-dependent diabetes mellitus,[12] the major defect in intracellular glucose processing is located in the nonoxidative pathway, that is, mainly glycogen synthesis. Because defects in this pathway also have been found in relatives of subjects with noninsulin-dependent diabetes mellitus, it may be the primary event in developing noninsulin-dependent diabetes mellitus (and syndrome X).

In obese subjects with noninsulin-dependent diabetes mellitus, the number of insulin receptors in skeletal muscle seems to be reduced. Furthermore, the ability of the insulin receptor kinase to stimulate external substrates is also reduced.[13] These two defects are common in obese persons with and without diabetes. Therefore the reduced receptor number and reduced kinase activity may not explain the difference in insulin action between the two groups. On the other hand, receptor abnormalities may at least in part explain the development of insulin resistance in obese subjects. Both defects may be of a secondary origin because they seem to be completely reversible by diet treatment.[14] The primary cellular defects responsible for the reduced insulin action in obese diabetic subjects must be located at the postreceptor level. One candidate could be the glucose transporter. Insulin-mediated glucose transport into muscle cells from obese persons with and without diabetes seems to be identical but reduced compared with lean control subjects.[15] However, reduced glucose transport activity may also be secondary because it can be induced by overfeeding and is completely reversible, at least in fat cells.[16] Furthermore, defects in insulin receptor number and kinase activity and in glucose transport activity cannot explain an isolated defect in the nonoxidative pathway. For that explanation, one needs specific defects in this pathway on the postreceptor and posttransporter level.

The key enzyme in glycogen synthesis is glycogen synthase. In lean subjects with normal glucose tolerance, that enzyme can be stimulated several fold by insulin, but in obese subjects the stimulation is significantly lower, and in obese diabetics, the enzyme activity is completely resistant to insulin.[17] That defect in glycogen synthase activity may explain the reduced glycogen synthesis in skeletal muscles from obese diabetic persons. Until now it has not been substantiated if it is the primary genetic defect.

In conclusion, insulin resistance in subjects with hypertension and noninsulin-dependent diabetes mellitus, and therefore supposedly also in subjects with syndrome X, seems mainly to be located in the nonoxidative pathway in skeletal muscles. Reduced glycogen synthase activity in skeletal muscles may be the primary defect in this syndrome. However, more studies are needed to emphasize that hypothesis.

Compensated insulin resistance may lead to syndrome X, whereas uncompensated insulin resistance in surplus leads to noninsulin-dependent diabetes mellitus.

Exogenous sex steroids, such as in the pill, may induce "syndrome X" by impairment of insulin action in skeletal muscles. However, the severity of this syndrome in pill users seem to be much less pronounced than in subjects with the genetic syndrome.

Role of plasma lipoproteins in the pathogenesis of atherosclerotic disease, with special reference to sex hormone effects

Matti J. Tikkanen, MD
Helsinki, Finland

Plasma lipoproteins constitute a complex lipid transport system. Very low–density lipoproteins transport triglycerides to peripheral tissues, whereas low-density lipoproteins are the main carriers of cholesterol. Cholesterol transported in low-density lipoprotein enters body cells by way of the "low-density lipoprotein receptor pathway" but may also be taken up by macrophages by way of the "scavenger pathway." Excessive influx of cholesterol by way of the "scavenger pathway" may result in deposition of cholesterol in arterial walls and atheroma formation. In a yet incompletely known process of "reverse cholesterol transport," cholesterol is carried away from the tissues to the liver by high-density lipoproteins. The above-mentioned transport processes are regulated by a well-synchronized system that involves several enzymes and lipid transport proteins. Under normal conditions, the lipoprotein system is able to balance the flow of cholesterol and other lipids in both directions between the liver and peripheral tissues. This delicate balance may be disturbed by many factors, including contraceptive steroids. The metabolic steps influenced by administration of contraceptive steroids are summarized. (AM J OBSTET GYNECOL 1990; 163:296-304.)

Key words: Oral contraceptives, cholesterol, lipoproteins, lipoprotein lipase, hepatic lipase

Lipids by themselves are not soluble in plasma. They are transported in the form of soluble complexes with proteins known as lipoproteins. Plasma lipoproteins constitute a carrier system that provides the tissues with lipids for production and storage of energy and with cholesterol needed for cellular structures and for synthesis of steroid hormones. With regard to pathogenetic mechanisms of atherosclerosis, a major advance was achieved when the metabolic steps involved in cholesterol delivery to body cells, a sequence designated the low-density lipoprotein receptor pathway, was clarified in detail.[1] Although less is known about the removal of excess cholesterol and lipid from peripheral tissues, a well-synchronized system involving several enzymes and lipid transport proteins, as well as high-density lipoprotein, probably regulates a "reverse cholesterol transport."[2]

Under normal conditions, the lipoprotein system is able to balance the flow of cholesterol (and other lipids) in both directions between the liver and peripheral tissues. However, this delicate balance may be disturbed by several factors, such as diet, drugs, and hormones. Some of these disturbances are known to cause the formation of atherosclerotic lesions in the arterial wall. Accumulation of low-density lipoprotein in plasma is a well-established cause of atherosclerosis. Low plasma high-density lipoprotein, which possibly reflects an alteration in "reverse cholesterol transport," may be another contributing factor. The present review is limited to the above-mentioned pathways of endogenous cholesterol transport, with special reference to metabolic steps influenced by the administration of contraceptive agents. The pathways involved in exogenous (dietary) lipid transport have been recently reviewed elsewhere.[3]

General outline of endogenous lipid transport

All lipoproteins share a common structure. Their surface layer consists of phospholipids and free cholesterol associated with protein components called apolipoproteins, whereas the lipophilic core region is filled with cholesteryl ester and triglycerides. In addition to chylomicrons that serve exogenous lipid transport, very low–density lipoprotein, low-density lipoprotein, and high-density lipoprotein can be separated from each other by sequential ultracentrifugation. High-density lipoprotein can be further separated into a light HDL_2 fraction and a denser HDL_3 fraction.

The liver provides triglycerides for peripheral tissues by secreting very low–density lipoprotein. The triglycerides are hydrolyzed and liberated from very low–density lipoprotein by the enzyme lipoprotein lipase,

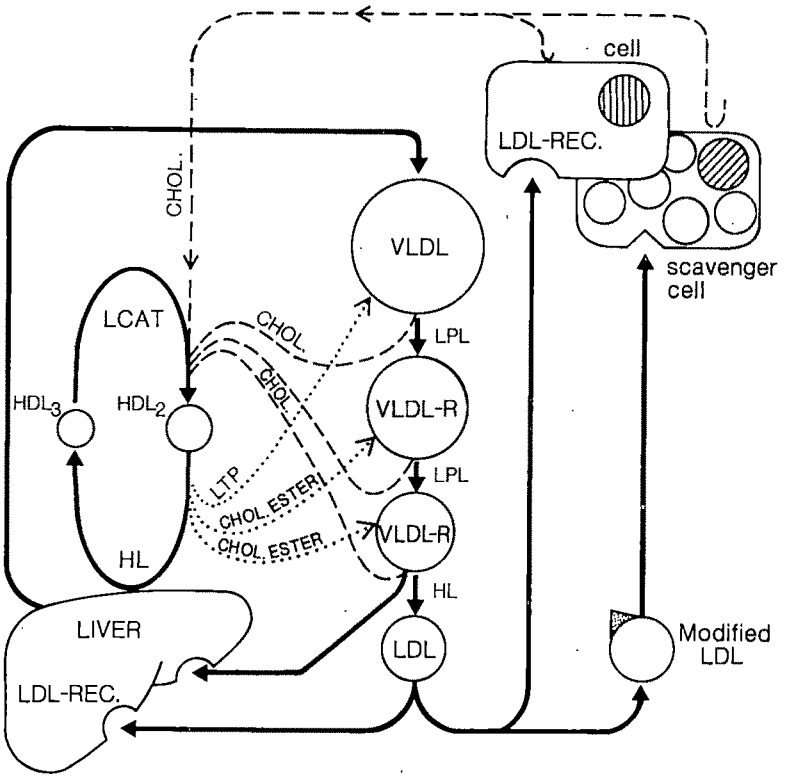

Fig. 1. Hypothetical scheme of cholesterol transport. *Dashed lines* indicate cholesterol flux from cells and lipolyzed very low-density lipoproteins *(VLDL)* and very low-density lipoprotein remnants *(VLDL-R)* to high-density lipoprotein 3 *(HDL_3)*, resulting in lecithin:cholesterol acyltransferase *(LCAT)*–catalyzed formation of HDL_2. *Dotted lines* indicate lipid transport protein *(LTP)*–mediated transfer of esterified cholesterol from HDL_2 to very low–density lipoprotein and VLDL-R, followed by conversion of HDL_2 into HDL_3 in a reaction catalyzed by hepatic lipase *(HL)*. *LPL*, Lipoprotein lipase; *LDL-REC*, low-density lipoprotein receptor.

which is attached to the endothelial cells in capillaries in extrahepatic tissues. The action of lipoprotein lipase promotes a gradual delipidation process in which smaller and denser remnants of very low–density lipoprotein (intermediate-density lipoproteins) are formed (Fig. 1). In addition to triglycerides, surface components (free cholesterol, phospholipids, and apolipoproteins except apolipoprotein B) are also removed from lipolyzed very low–density lipoprotein and transferred to high-density lipoprotein. Finally, small remnants of very low–density lipoprotein are converted into low-density lipoprotein, a step in which another enzyme, hepatic lipase, has a yet ill-defined role.

The function of low-density lipoprotein is to deliver cholesterol to body cells by way of the low-density lipoprotein receptor pathway. This pathway is initiated by the recognition and binding of the sole protein component in low-density lipoprotein, apolipoprotein B, to the low-density lipoprotein receptor. Body cells maintain their intracellular cholesterol homeostasis by up- or down-regulation of the number of low-density lipoprotein receptors on cell surfaces.[1,4]

High-density lipoprotein provides a mechanism for the removal of cholesterol from extrahepatic tissues to the liver. The free cholesterol derived from cells and from other lipoprotein classes is incorporated into the surface layer of HDL_3 particles where it becomes esterified in a reaction that is catalyzed by lecithin:cholesterol acyl transferase,[5] an enzyme activated by apolipoprotein A_1, the main apolipoprotein in high-density lipoprotein. The lecithin:cholesterol acyl transferase reaction contributes to the formation of larger, less-dense HDL_2 particles. The cholesteryl esters contained in HDL_2 are then transported to the liver by direct or indirect routes (Fig. 1).

Very low–density lipoprotein and triglyceride metabolism

Lipolysis of very low–density lipoprotein. In 1953 Nikkilä[6] observed that an intravenous heparin injection released a "clearing factor" into the circulation that caused a shift in lipids from β-globulins to α-globulins (from lower density lipoproteins to high-density lipoprotein) and resulted in a distribution of lipids "opposite to that found in many pathological states, that is, in atherosclerosis." This was an early description of the very low–density lipoprotein lipolytic process in

which clearing factor or lipoprotein lipase (releasable into the circulation by heparin) serves as a rate-limiting enzyme of very low–density lipoprotein catabolism. Hydrolysis of triglycerides by lipoprotein lipase results in shrinkage of the lipoprotein core, a situation in which the surface layer becomes too large and redundant. Its surplus constituents (free cholesterol, phospholipid, and apolipoproteins C and E) are pinched off the particles as discoidal structures,[7] which, on entering the plasma compartment, are rapidly converted into spherical high-density lipoprotein particles by the lecithin: cholesterol acyl transferase reaction. Alternatively, surplus material is taken up by preexisting HDL_3 particles, which result in formation of HDL_2 particles by lecithin: cholesterol acyl transferase. With the continuous loss of both core and surface lipids, very low–density lipoprotein remnant (intermediate-density lipoprotein) particles gradually diminish in size and ultimately give rise to low-density lipoprotein molecules (Fig. 1).

Although the precursor-product relationship between very low–density lipoprotein and low-density lipoprotein is beyond doubt, all very low–density lipoprotein does not generate low-density lipoprotein. Large triglyceride-rich very low–density lipoproteins are rapidly cleared from the circulation by the liver by way of a receptor-mediated process with relatively little conversion into low-density lipoprotein. Smaller very low–density lipoprotein particles containing less triglycerides and more cholesterol are more efficiently converted into low-density lipoproteins.[8, 9]

Several lines of evidence indicate that another lipolytic enzyme, hepatic lipase, located on the endothelial cells in liver sinusoids,[10] also participates in the very low–density lipoprotein–lipolytic process that converts very low–density lipoprotein remnants to low-density lipoprotein. This is suggested by studies that indicate accumulation of very low–density lipoprotein remnants during hepatic lipase inhibition in animals,[11-16] as well as in humans with inherited hepatic lipase deficiency.[17-19] A negative correlation was reported to exist between hepatic lipase activity and intermediate-density lipoprotein in patients with hyperlipidemia.[20] Large low-density lipoprotein enriched with triglycerides has been a common finding in patients with familial hepatic lipase deficiency,[17-19] possibly representing the final product of very low–density lipoprotein catabolism in these patients.[19]

Lipid transfer proteins and very low–density lipoprotein lipolysis. Plasma lipid transfer proteins promote a reciprocal exchange of triglycerides from very low–density lipoprotein with cholesteryl esters derived from high-density lipoprotein.[21, 22] The lipid transfer proteins also probably facilitate transfer of phospholipids from very low–density lipoprotein to high-density lipoprotein during lipolysis.[22] Lipolysis of triglyceride-rich lipoproteins is a major source of high-density lipoprotein phospholipids.[23] Enhanced activity of lipid transfer proteins has been demonstrated during in vitro lipolysis, probably because of preferred binding of lipid transfer proteins to lipolyzed (compared with nonlipolyzed) lipoproteins.[24] Similar mechanisms could operate in vivo, facilitating transfer of lipids from lipoproteins undergoing lipolysis to acceptor high-density lipoprotein.[22] Moreover, the lipid transfer proteins mediate a continuous core-lipid exchange, providing a constant flux of esterified cholesterol to the triglyceride-rich lipoproteins and triglycerides to high-density lipoprotein.

As delineated, in additon to supplying tissues with free fatty acids and partially hydrolyzed glycerides, very low–density lipoprotein catabolism generates low-density lipoprotein for cholesterol transport by way of the low-density lipoprotein receptor pathway. Moreover, very low–density lipoprotein catabolism gives rise to HDL_2 particles, which are involved in transporting cholesterol in the opposite direction. These pathways will be discussed.

Cholesterol transport

The low-density lipoprotein receptor pathway. Our understanding of the pathogenesis of hypercholesterolemia and its role in atherosclerosis development has been facilitated by the studies of Brown and Goldstein,[4, 25] who used familial hypercholesterolemia as a model. They convincingly demonstrated the crucial role of regulation of plasma low-density lipoprotein in body cholesterol transport. Low-density lipoprotein was shown to mediate the delivery of cholesterol to body cells by way of the low-density lipoprotein receptors possessed by almost all types of cells.[26] Initially, the low-density lipoprotein bound to the low-density lipoprotein receptor, was internalized together with the receptor, and was exposed to lysosomal enzymes that hydrolyzed the low-density lipoprotein particles, releasing free cholesterol in the cytoplasm. This incoming free cholesterol was found to exert the following three regulatory effects that served to maintain intracellular cholesterol homeostasis: (1) The released cholesterol suppressed the activity of the 3-hydroxy-3-methylglutaryl coenzyme A reductase, which is the rate-limiting enzyme of cholesterol synthesis; (2) the activity of acyl coenzyme A:cholesterol acyltransferase, which reesterifies excess cholesterol for storage as lipid droplets in the cytoplasm, was activated; and (3) the liberated cholesterol suppressed low-density lipoprotein receptor synthesis, preventing further influx of cholesterol.[1]

The low-density lipoprotein receptor concept ex-

plains how the cells are able to increase their uptake of cholesterol, if necessary, by increasing the synthesis of low-density lipoprotein receptors. Conversely, cells are able to down-regulate their LDL receptors when intracellular cholesterol concentration is increasing. The most common reason for down-regulation of low-density lipoprotein receptors in Western populations is a diet rich in cholesterol and saturated fat, which causes the hepatocytes to accumulate cholesterol. In an analogy to inherited low-density lipoprotein receptor deficiency (familial hypercholesterolemia), the reduced number of low-density lipoprotein receptors in the liver causes an elevated plasma concentration of low-density lipoprotein, which is detected as elevated plasma cholesterol. Because most of the circulating low-density lipoprotein is cleared by way of the liver, impairment of this route has important consequences. As will be discussed, low-density lipoprotein that has been denied the receptor-mediated pathway may undergo modification and be cleared by way of a low-density lipoprotein receptor-independent pathway, the "scavenger pathway."

The "scavenger pathway" and atheroma formation.

Turnover studies[27-30] indicated that in normal and receptor-deficient subjects, some of the low-density lipoprotein was removed from the circulation by way of a low-density lipoprotein receptor-independent pathway designated "the scavenger pathway." Monocyte-derived macrophages residing in arterial walls probably constitute an important part of the scavenger cell system.[25, 31] In addition to the low-density lipoprotein receptor, macrophages have receptors that recognize chemically modified low-density lipoprotein. Unlike the low-density lipoprotein receptor, the "scavenger receptor" is not down-regulated by increasing the cellular cholesterol content, thus allowing these cells to become engorged with esterified cholesterol.[32] During excessive influx of modified low-density lipoprotein, the cells assume the characteristic of "foam cells" filled with cytoplasmic lipid droplets. Several mechanisms operating in the arterial intima are able to modify low-density lipoprotein to promote its uptake by macrophages.[31] The cholesteryl esters stored in lipid droplets are continuously undergoing hydrolysis[33] and can probably be excreted from the cell if cholesterol acceptors (e.g., high-density lipoprotein) are available.

Development of the earliest atherosclerotic lesion, the fatty streak, is characterized by the accumulation of "foam cells" beneath the arterial endothelium. If the influx of low-density lipoprotein–derived cholesterol into the arterial wall is not balanced by an adequate cholesterol removal mechanism, the ability of scavenger cells to excrete the cholesterol is overwhelmed and atherosclerosis develops. These events have recently been comprehensively reviewed.[31]

High-density lipoprotein and reverse cholesterol transport

Origin of plasma high-density lipoprotein. Nascent high-density lipoprotein enters the plasma compartment as discoidal bilayer structures that contain mostly phospholipids, unesterified cholesterol, and apolipoprotein. Nascent high-density lipoprotein is secreted by the liver and intestine or is derived from lipolyzed very low–density lipoprotein (or chylomicrons).[34, 35] In the plasma compartment the bilayers are rapidly converted into spherical particles through the action of lecithin:cholesterol acyl transferase, which esterifies free cholesterol with fatty acid from the phospholipid lecithin. The cholesteryl ester molecules move between the layers and form a hydrophobic core, giving rise to small spherical particles in the HDL_3 density range.[7]

HDL subfractions. After maturation of nascent high-density lipoprotein to HDL_3 particles, these particles serve as acceptors for additional free cholesterol and phospholipids, both of which serve as substrate for the lecithin:cholesterol acyl transferase reaction. These constituents are derived from lipolyzed triglyceride-rich lipoproteins and from body cells. Uptake of cholesterol by high-density lipoprotein from peripheral cells may be by assimilation from cellular membranes or mediated by high-density lipoprotein receptors recognizing apolipoprotein A_1.[36] Such receptors are up-regulated by accumulation of intracellular cholesterol.[37, 38] With continuous flux of esterified cholesterol into the lipoprotein core, particle size increases and the average density shifts into the HDL_2 range. Although HDL_2 is formed by the combined effects of lipoprotein lipase and lecithin:cholesterol acyl transferase previously described, HDL_2 can be reconverted to HDL_3 by the combined effects of hepatic lipase and lipid transfer proteins (Fig. 1).

Alterations in plasma total high-density lipoprotein cholesterol concentration usually reflect alterations in HDL_2, which appears to be the subfraction sensitive to dietary, hormonal, and other perturbations. In contrast, HDL_3 cholesterol concentrations tend to remain stable or are much less modified. Major mechanisms involved in regulation of plasma high-density lipoprotein concentration will be discussed.

Rate of very low–density lipoprotein lipolysis in the regulation of high-density lipoprotein. Several studies have revealed a positive correlation between post-heparin plasma or adipose tissue activity of lipoprotein lipase and high-density lipoprotein cholesterol.[39-42] On this basis, it appears that the rate of very low–density

lipoprotein (and chylomicron) lipolysis is an important regulator of the plasma high-density lipoprotein level.[42, 43] This is supported by a variety of experiments in which lipoprotein lipase activity was stimulated (by administration of fat, alcohol, or insulin or by physical exercise) or suppressed (by diets low in fat or caloric intake and by insulin deficiency or insulin resistance) and in which changes in opposite directions occurred in high-density lipoprotein or HDL_2 but not in HDL_3.[44] Thus the high-density lipoprotein and HDL_2 concentrations may be low in patients with hypertriglyceridemia because of low lipoprotein lipase activity, which causes reduced flux of surface constituents that are used in HDL_2 formation. However, this does not explain why the high-density lipoprotein concentration may be low in patients with hypertriglyceridemia resulting from increased production of very low–density lipoprotein in the presence of normal lipoprotein lipase activity. To explain this, two other factors, lipid transfer protein activity and hepatic lipase ativity, must be considered.

Rate of cholesteryl ester transfer in the regulation of high-density lipoprotein. The lipid transfer protein mediates the transfer of cholesteryl ester from high-density lipoprotein to triglyceride-rich lipoproteins in exchange for triglycerides from these particles.[21, 22] Thus cholesteryl esters originating from the lecithin:cholesterol acyl transferase reaction in high-density lipoprotein are transported to very low–density lipoprotein and ultimately to low-density lipoprotein derived from very low–density lipoprotein catabolism. This provides a route of cholesterol transport from extrahepatic tissues to the liver. The rate of cholesteryl ester transfer from high-density lipoprotein is proportional to the amount of very low–density lipoprotein present at least during incubation in vitro.[45] If the same mechanism works in patients with hypertriglyceridemia, the result is formation of high-density lipoprotein that is deficient in cholesteryl ester and enriched in triglyceride. Since triglycerides provide a good substrate for hepatic lipase, the net result is a reduction in both core lipids, resulting in small, dense particles that resemble HDL_3. This could explain the occurrence of low high-density lipoprotein (HDL_2) cholesterol in subjects with hypertriglyceridemia with an increase in production of very low–density lipoprotein but normal lipoprotein lipase function.

Hepatic lipase in the regulation of high-density lipoprotein. The role for hepatic lipase in the degradation of high-density lipoprotein was suggested by studies showing an inverse relationship between hepatic lipase activity in postheparin plasma and the concentration of high-density lipoprotein or HDL_2.[46-50] Experimental studies suggested that HDL_2 was selectively degraded by hepatic lipase[51-54] and that inhibition of this enzyme in rats produced elevated levels of high-density lipoprotein.[55] Clinical studies[56, 57] have indicated that hepatic lipase is a sex steroid–sensitive enzyme suppressed by estrogen and stimulated by steroids with androgenic activity. Manipulations of postheparin plasma hepatic lipase activity by administration of a variety of sex steroids have shown that fluctuations in enzyme activity were, as a rule, accompanied by reciprocal changes in HDL_2 cholesterol levels.

It should be pointed out that removal of HDL_2 triglycerides (and probably phospholipids) by hepatic lipase is not sufficient to produce HDL_3 particles. Particles must also release large amounts of cholesteryl ester, which can be accomplished by the lipid transfer protein–mediated mechanism previously described. Together, these mechanisms contribute to reconverting HDL_2 into HDL_3 (Fig. 1). In addition, experimental studies have suggested that esterified cholesterol may be released directly from high-density lipoprotein particles to hepatocytes, or receptor-mediated uptake of high-density lipoprotein particles into the liver may occur.[58]

In hypertriglyceridemia, enhanced core-lipid exchange produces triglyceride-rich high-density lipoprotein that is efficiently hydrolyzed by hepatic lipase. This accounts for the common finding of a reduced high-density lipoprotein cholesterol level, with predominantly small particles in the HDL_3 density range.

Lecithin:cholesterol acyl transferase activity in the regulation of high-density lipoprotein. Lecithin:cholesterol acyl transferase catalyzes the esterification of free cholesterol on the surface of lipoproteins the preferred site being the surface of high-density lipoprotein, particularly the more dense particles in the HDL_3 subfraction.[59] Subsequently, the cholesteryl esters are incorporated into the lipophilic core of high-density lipoprotein, creating a concentration gradient for acquisition of more free cholesterol arriving from body cells and other lipoprotein fractions. Further action by lecithin:cholesterol acyl transferase, along with acquisition of other constituents from the very low–density lipoprotein lipolytic pathway, results in the development of larger and less dense HDL_2 particles (Fig. 1).

Mechanisms of "reverse cholesterol transport." Unesterified cholesterol is continuously moving from cells and lipoprotein surfaces to the surface of high-density lipoprotein. This cholesterol efflux is maintained by a concentration gradient that is generated when lecithin:cholesterol acyl transferase–derived cholesteryl esters are displaced from the high-density lipoprotein surface into the core and subsequently removed from high-density lipoprotein by lipid transfer protein activity. Alternatively, high-density lipoprotein particles may bind to high-density lipoprotein receptors while incorporating cellular cholesterol.[36] Receptors in-

volved in this process recognize apolipoprotein A_1 and are up-regulated when intracellular cholesterol concentration increases.[37] Cell culture studies have suggested that such high-density lipoprotein receptor-mediated removal of unesterified cholesterol occurs from macrophages that have accumulated modified low-density lipoprotein.[38]

Esterification of cholesterol by lecithin:cholesterol acyl transferase followed by a constant redistribution by lipid transfer proteins of cholesteryl esters to the very low–density lipoprotein −>low-density lipoprotein pathway maintains a continuous flow of cholesterol moving from the periphery to the low-density lipoprotein receptor pathway. Cholesteryl esters may arrive in the liver as components of very low–density lipoprotein remnants that are taken up by low-density lipoprotein receptors, or they may be retained in particles converted to low-density lipoprotein, also to be taken up by low-density lipoprotein receptors, thus ultimately completing a cycle of "reverse cholesterol transport."

Other mechanisms may also be important in "reverse cholesterol transport." Apolipoprotein E–containing high-density lipoprotein (a subfraction in the HDL_2 density range) binds hepatic low-density lipoprotein receptors and E receptors and therefore may be taken up by the liver.[60] Also, other types of receptor-mediated uptake have been suggested.[58] Experimental studies have demonstrated that pretreatment of high-density lipoprotein particles with hepatic lipase stimulates uptake of cholesterol from high-density lipoprotein to hepatoma cells.[61, 62] However, transfer was limited mainly to unesterified cholesterol[62] and did not indicate significant cholesteryl ester flux.

Low-density lipoprotein, high-density lipoprotein, and the development of atherosclerosis

During accumulation of low-density lipoprotein in plasma caused by overproduction or insufficient clearance by the low-density lipoprotein receptor pathway, large numbers of low-density lipoprotein molecules find their way through the endothelial lining of arterial walls. As previously described, low-density lipoprotein may undergo modification, which enables macrophages and smooth muscle cell to internalize them. Accumulation of lipid-laden "foam cells" and the inability of "reverse cholesterol transport" mechanisms to remobilize the cholesteryl esters probably initiate the atherosclerotic process.

Although there is no doubt about the atherogenicity of elevated plasma low-density lipoprotein cholesterol levels, the role of plasma high-density lipoprotein cholesterol concentration as an indicator of "reverse cholesterol transport" efficacy remains unresolved. It is usually thought that high high-density lipoprotein concentration indicates high cholesterol removal capacity from peripheral tissues, including arterial walls. Indeed, an abundant presence of high-density lipoprotein acceptor molecules for receptor-mediated or receptor-independent removal of cholesterol from lipid-filled macrophages and smooth muscle cells would obviously promote the initial step of "reverse cholesterol transport," and be in line with epidemiologic evidence indicating that elevated high-density lipoprotein cholesterol protects against atherosclerosis.[63]

On the other hand, a *low* high-density lipoprotein cholesterol level associated with increased atherosclerosis risk may also, in some situations (e.g., in hypertriglyceridemia), reflect increased "reverse cholesterol transport." This indicates that an enhanced rate of "reverse cholesterol transport" cannot be unequivocally regarded as an antiatherogenic phenomenon. In fact it has been suggested that efficient transfer of esterified cholesterol to potentially atherogenic lipoproteins (very low–density lipoprotein and low-density lipoprotein) could promote atherosclerosis.[22]

Metabolic steps influenced by the administration of contraceptive steroids

Very low–density lipoprotein and triglyceride metabolism. Most previous studies indicate the following: (1) that contraceptive estrogens elevate plasma very low–density lipoprotein and triglyceride levels, (2) that androgenic progestins derived from 19-nortestosterone reduce plasma very low–density lipoprotein and triglyceride levels, whereas progesterone-derived progestins have little effect, and (3) that in combination preparations, the relative potencies of estrogen and progestin determine the net effect on plasma very low–density lipoprotein and triglyceride levels.[56] The plasma triglyceride-elevating effect increases with estrogen dose[64-66] and is opposed more effectively by androgenic progestins (e.g., levonorgestrel) than by nonandrogenic progestins (e.g., desogestrel).[67, 68]

The plasma triglyceride-elevating effect of estrogens is the result of increased production of very low–density lipoprotein,[69-71] whereas no reduction in very low–density lipoprotein clearance has been reported.[69-72] Purely androgenic steroids are known to stimulate removal of plasma triglycerides,[73, 74] and there is some evidence for a similar effect produced by estrogen-progestin combinations.[70, 71] Plasma triglyceride effects are not mediated by changes in lipoprotein lipase activity.[56] It is not clear whether up- and down-regulation of hepatic lipase activity by estrogen and progestin contributes significantly to alterations in plasma very low–density lipoprotein and triglyceride levels during oral contraception.

Metabolism of low-density lipoprotein. In estrogen deficiency (postmenopausal women, men) marked

suppression of plasma low-density lipoprotein cholesterol usually occurs during the administration of estrogen.[56, 75] This has been attributed to estrogen-induced stimulation of low-density lipoprotein receptor activity demonstrated in animal[76, 77] and cell culture[78] experiments. However, premenopausal women respond differently, with no reduction in low-density lipoprotein cholesterol during contraceptive estrogen administration.[69]

Most of the earlier combination oral contraceptives tended to increase plasma concentration of low-density lipoprotein cholesterol.[79] The elevation was smaller with "estrogen-dominant" preparations than with "progestin-dominant" preparations[79] and greatest with preparations containing androgenic progestin.[80] The mechanisms behind the low-density lipoprotein–elevating effect of androgenic progestins[68] has not been clarified. Theoretically, stimulation of hepatic lipase activity by androgenic steroids could facilitate conversion of very low–density lipoprotein remnants to low-density lipoprotein. In association with estrogen-induced stimulation of very low–density lipoprotein production, this could result in low-density lipoprotein elevation. Alternatively, progestins might act as antiestrogens down-regulating low-density lipoprotein receptor activity. Neither of these possibilities has been explored adequately.

The content of triglycerides in low-density lipoprotein is increased with most oral contraceptive preparations.[64] This triglyceride-enriched low-density lipoprotein differs from the large buoyant low-density lipoprotein reported in hepatic lipase deficiency states[19] by manifesting a decreased flotation rate.[81, 82] Such a compositional change could result from increased lipid transfer protein–mediated exchange of cholesteryl ester and triglyceride between very low–density lipoprotein and low-density lipoprotein. This would probaby occur if the amount of circulating triglyceride-rich lipoproteins is increased during oral contraceptive administration.

Metabolism of high-density lipoprotein. Alterations in plasma total high-density lipoprotein cholesterol concentration during the administration of different oral contraceptives are caused mainly by alterations in the steroid-sensitive subfraction HDL_2.[49, 56, 83] Estrogens cause an elevation of HDL_2, whereas progestins with androgenic activity have the opposite effect. The relative potencies of estrogen and androgen determine the net result.[56] Estrogens act by at least two mechanisms: suppression of hepatic lipase activity, causing reduced conversion of HDL_2 into HDL_3, and increased synthesis of apolipoprotein A_1.[69] Androgenic progestins stimulate hepatic lipase activity,[83] and androgens suppress synthesis of apolipoprotein A_1,[84] which explains why estrogen-induced high-density lipoprotein elevations may be opposed or overwhelmed by the progestin component in oral contraceptives. Elevation of plasma very low–density lipoprotein produced by many oral contraceptives promotes lipid transfer protein–mediated removal of cholesteryl ester from high-density lipoprotein, which also contributes to decreased plasma high-density lipoprotein cholesterol. As previously discussed, it is unclear whether effective "reverse cholesterol transport" is antiatherogenic. Even if it were, its effectiveness could not be judged on the basis of plasma high-density lipoprotein cholesterol concentration. Thus the clinical significance of high-density lipoprotein cholesterol fluctuations induced by oral contraceptives remains uncertain.

The great majority of reported studies concerns earlier generations of oral contraceptives. Therefore some of the results may be irrelevant with regard to newer low-estrogen, low-progestin preparations, which have little effect on plasma low-density lipoprotein or high-density lipoprotein cholesterol.[85]

Disorders of the hemostatic system and the risk of the development of thrombotic and cardiovascular diseases: Limitations of laboratory diagnosis

Cornelis Kluft, PhD
Leiden, The Netherlands

The relationship between hemostatic abnormalities and thrombotic and cardiovascular diseases is summarized. All known congenital and acquired abnormalities in the biochemistry of hemostasis are related to thrombotic and cardiovascular diseases in the way that would be expected on the basis of theories about the role of balances between coagulation and fibrinolysis and between activating and inhibiting factors. Notwithstanding the consistency between theory and observed abnormalities, a causal relationship between biochemical abnormality and clinical symptoms has been proved only in a limited number of situations, and it is possible that certain abnormalities only (or also) mark pathologic events. The limitations of laboratory diagnosis of hemostatic disorders in relation to hemostasis as a local process are discussed. It is proposed that more attention be paid to methods of evaluating the local aspects, for example, methods that assess reaction products in the circulation and that can provide an averaged message of the local phenomena. In addition, such methods can provide information about the dynamic balances in the hemostatic system, whereas historically more attention has been paid to the static balances in the potential of hemostatic processes. (AM J OBSTET GYNECOL 1990;163:305-12.)

Key words: Fibrinolysis, coagulation, cardiovascular diseases, hemostatic disorders

The reaction to damage or trauma can result in the formation of platelet or fibrin deposits for temporary function in hemostatic plugging and support of cell growth in subsequent tissue repair. The formation and dissolution of the deposits are usually carefully regulated, and ideally the occurrence is confined to the exact time when the deposits are needed. Abnormalities in either direction of defective or excessive deposit formation are known. In addition to abnormalities in tissue repair (e.g., organized thrombi, deformations in persons with hemophilia,[1] excessive scar formations, and induced damage, such as valve destruction), overt symptoms such as either thrombosis or bleeding can occur.

The process of platelet or fibrin formation can be triggered by tissue damage and trauma. Moreover, next to clearcut macro damages, such as bruises and cuts, it has been proposed that micro damages occur continuously in the body.[2] Such micro damages might be at the level of single cells. It is suggested that they occur frequently in normal life and result in an almost continuous low-grade action of the coagulation system. To counteract this low-grade coagulation action, the fibrinolytic system should similarly exert an almost continuous low-grade action. The work of Astrups[2] implies that in regard to their potential, the fibrin-forming and removing systems should be in balance, as well as in their low-grade action. In other words, we can distinguish two balances: the static balance in potential and the dynamic balance in action.[3]

Hemostatic disorders and clinical implications

Congenital disorders. Several hereditary hemostatic disorders have been identified that usually affect the performance of a single factor and cause either bleeding or venous thrombosis. In recent years it has become apparent in the Netherlands that the occurrence of hereditary thrombophilia has a higher provisionally estimated prevalence (1:3000) than the much earlier and better known hemophilia (1:15,000).[4,5]

We can group these hereditary hemostatic disorders into categories on the basis of known mechanisms. As shown in Fig. 1, *A*, a balance between coagulation and fibrinolysis puts these two processes in opposite situations. Defective coagulation results in bleeding, but defective fibrinolysis results in thrombosis, whereas bleeding can be induced by excessive fibrinolysis or defective coagulation. For all aspects, multiple examples of hereditary single-factor deficiencies are available (Tables I and II).

A balanced approach can be extended as shown in Fig. 1, *B*, to a balance within each system. Both the coagulation and fibrinolytic systems are cascade types of processes, in which activation is achieved by appro-

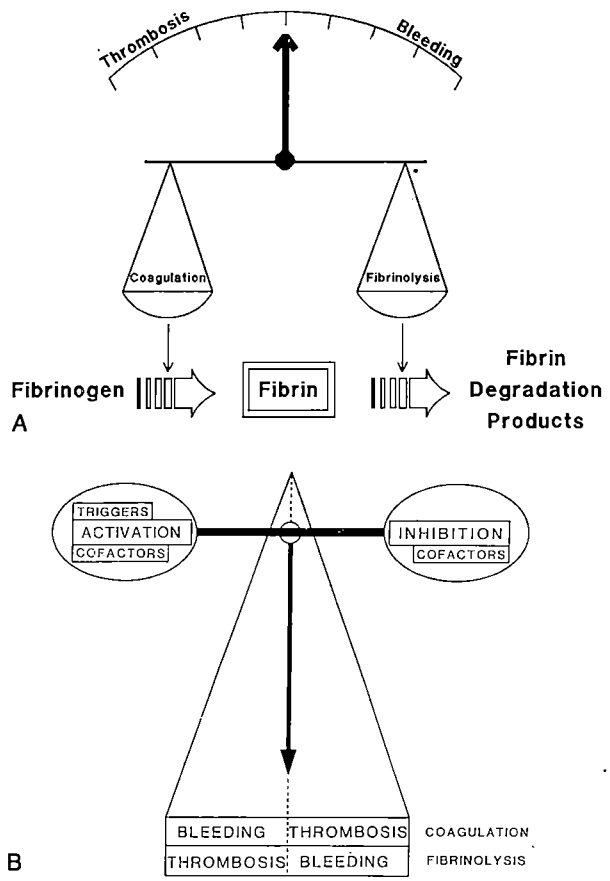

Fig. 1, A-B. Balances between the systems of coagulation and fibrinolysis and between activating and inhibiting components of these systems in relation to clinical symptoms of thrombosis and bleeding in case of imbalance.

priate limited proteolysis or conformational changes and in which damping is achieved by inactivation. Both opposing actions (activation and inhibition) can have cofactors for action, and activation requires triggering. In Fig. 1, *B*, the balance within the system is expressed in a cartoon, which shows both the opposite actions of activity promoting factors and inhibitory factors and the opposite positions of coagulation and fibrinolysis.

In Tables I and II known single-factor deficiencies in coagulation (except platelets) and fibrinolysis are divided into two clinical categories: bleeding and thrombosis. Fibrinogen is discussed separately (see below). For the threshold levels shown in Tables I and II, above or below which clinical effects become relevant, the choice of one clinician/author is cited where possible.[6]

The data in Tables I and II mainly concern venous thrombosis, since knowledge of arterial thrombosis in relation to single-factor deficiencies is scanty.[7-10] For dysfibrinogenemia, a clearcut relationship exists between arterial thrombosis and single-factor abnormality,[10] whereby expression of both arterial and venous thromboembolic complications can occur in one family or patient. Recently in young adults with arterial occlusive disease, protein S deficiency has also been found (8%), but no protein C or clear antithrombin III deficiency.[7] Evidence of a protective effect has been given for single-factor deficiencies in factor VIII or von Willebrand factor.[11] Conversely, elevations in the levels of these factors have been observed regularly, such as in 24% of patients with early (before 45 years) onset of arterial occlusive disease.[7]

Knowledge about the relationship between single-factor deficiencies and venous thrombosis has been obtained largely by the study of familial venous thrombosis. Similar studies on familial arterial thromboembolic complications are also needed for this aspect of arterial thrombosis. So far the selection of patients for venous thrombosis has not resulted in a large overlap with arterial thrombotic complications. In a study on venous thrombosis performed in the Netherlands, only 3% of patients had both arterial and venous thromboembolic problems, most of which were related to dysfibrinogenemia.[4] It should be evaluated whether this finding indicates that venous and arterial diseases are related to different biochemical deficiencies in hemostasis (option 1). It is also possible that deficiencies in biochemical hemostasis are equally important for both venous and arterial symptoms but that other factors determine whether the expression is venous or arterial (option 2). The identification of such a putative essential difference in the pathogenesis of hemostatic disorders would be an important goal of future research. In the near future, further knowledge about familial arterial disease will be needed. The families of young adults with arterial occlusive disease and protein S deficiency[7] should be studied to explore whether option 2 occurs for protein S.

Risk markers. For arterial disease, alterations in several variables of hemostasis have prognostic value. These alterations are indicated in Tables I and II as "prognostic significance" (PS). The major hemostatic deviations associated with arterial diseases are increased fibrinogen, increased factor VIIc, and increased activity of plasminogen activator inhibitor-1 (PAI-1)/decreased tissue-type plasminogen activator (t-PA) activity.[12-23] Theoretically these alterations can cause increased coagulation or reduced fibrinolysis in keeping with pathogenetic theories. However, it is possible that the alterations are not causal to the clinical expression but merely reflect an underlying mechanism or are consequences of other alterations and function as markers.

In the balance between coagulation and fibrinolysis, fibrinogen plays a central role, with the possibility that abnormalities change the balance in both directions of clinical symptoms (Fig. 1, *A*). Patients with congenitally abnormal fibrinogens (dysfibrinogenemia) can either

Table I. Deviations in the coagulation system in relation to symptoms

Coagulation					
Bleeding	*Thrombosis*		*Bleeding*	*Thrombosis*	
	Activation			Inhibition	
<40%	II			AT III	<75%

<25%	IX			—	
<30%	X				
<50%	XI				
‡	XII	<50%‡			
	PK				
	KNG				
	—				

The indicated values are percentages of normal and are threshold levels for clinical expression (see text). When no mark or level is indicated for a factor in one of the categories, a deviation assocated with hemostatic disorders is not present or knowledge is absent or controversial at present.

vWF, von Willebrand factor; *PK,* prekallikrein; *KNG,* kininogen; *AT III,* antithrombin III; *PS,* prognostic significance.

*Elevated levels are frequently found in groups with venous[4] and arterial thromboembolic diseases,[7, 64] and reduced levels appear protective.[11]

†Protein C deficiency is clinically dominant in about 5% of heterozygous cases[4, 65] and clinically recessive for other heterozygotes.[66]

‡Bleeding in homozygous factor XII deficiencies is rare.[67] In families with members with around 40% factor XII, a thrombotic diathesis has been observed.[68] (See text and other sources.[12, 64, 69, 70])

Table II. Deviations in the fibrinolytic system in relation to symptoms

Fibrinolysis					
Bleeding	*Thrombosis*		*Bleeding*	*Thrombosis*	
	Activation			Inhibition	
	plasminogen	<65%	<80%	α_2-AP	
*	t-PA	↓ PS†	<5%	XIII	
	u-PA		‡	PAI-1	↑ PS
	—			HRG	>145%
				PAI-2	
				—	

The indicated values are percentages of normal and are threshold levels for clinical expression (see text).

When, for a factor, no level or prognostic significance is indicated in one of the categories, deviation associated with hemostatic disorders is not present or knowledge is absent or controversial at present.

*Anecdotal reports indicate that elevated t-PA activity[71, 72] relates to a bleeding diathesis.

†Ten percent to 12% of patients with venous thrombophilia have an abnormally low response in the venous occlusion test,[73, 74] which an abnormality relates to a poor prognosis for recurrences,[74] and this abnormality shows familial clustering,[75] or according to preliminary data, may have a genetic cause.[76]

‡Two situations with abnormally low PAI-1 and a bleeding diathesis have been reported.[77, 78] (See text and other sources.[22, 23, 79-81])

have no symptoms (the majority of known cases), a tendency to bleed (one third of cases), or a tendency to develop thrombosis (20%), depending on the abnormality in the fibrinogen molecule.[10] Consistent with the theories, the tendency to develop thrombosis has been explained in two cases by an abnormality in the function of fibrinogen in the regulation of fibrinolysis.[24, 25]

High plasma fibrinogen levels are recognized further in most studies as an important risk marker for ischemic heart disease[12-16] and nonhemorrhagic stroke.[13, 20] Increased fibrinogen levels have also been observed in asymptomatic peripheral arterial disease[18] and in patients after myocardial infarction,[26] especially in those with recurrencies.[17] They correlate with the angiographic score in one study[19] but not in another.[27] In addition to the demonstration of fibrinogen as a risk marker, it is also believed to have a causal role in cardiovascular disease. This is related to the effects of high fibrinogen levels on viscosity,[28] platelet aggregation,[29] and thrombus size.[30] High fibrinogen levels also affect the amount of fibrinogen in the vessel wall, which results in an increase in the accumulation of fibrin when coagulation occurs.[31, 32] The amount of fibrin in lesions is indeed increased[33] and can act as a diffusion block.[34] It can contribute to atherosclerosis by cuffing of vessels,

resembling perivascular manipulation, which produces a very rapid development of atherosclerosis in animals.[35] The establishment of high fibrinogen levels as a risk factor rather than as a marker still requires that interventions in the levels have an effect.

Possible double function of risk markers. For the relationship between abnormalities in the variables of hemostasis and clinical symptoms (Tables I and II), all the alterations in the biochemistry of hemostasis are theoretically consistent with the clinical symptoms. Nevertheless, this consistency does not necessarily imply that all alterations are causally related to the clinical symptoms. However, causal relationship is not excluded but in most circumstances is not proved. According to the criteria for establishing a relationship between congenital defect and venous thrombophilia,[5] sufficient evidence has been provided only for antithrombin III and proteins C and S deficiency.[5] In other cases evidence is still being gathered. In various situations the alterations may only be markers of an underlying mechanism.

The presence of such remarkable consistency between abnormality and expected symptoms presents the third alternative that markers are contributing to aggravation of the symptoms at the same time. In this latter combination, a strict distinction between causal factors and markers is no longer relevant.

It has recently been proposed to group a particular set of alterations together into what has been called "syndrome X."[36] In this syndrome, a link has been proposed between insulin resistance (as an underlying common pathway) and central obesity, hypertension, increased triglycerides, and decreased high-density lipoprotein. Elevations in PAI-1 can also be added to this syndrome. As shown by Juhan-Vague et al.,[37, 38] there is a clear correlation between insulin, triglycerides, and PAI-1. Insulin has been shown to increase PAI-1 production by hepatocytes.[39, 40] We can also add to this, further mechanistic links with hemostasis. Thus insulin increases the synthesis in cultured hepatocytes of fibrinogen after prolonged exposure.[41] In addition, a link between triglycerides (mainly the composition and presence of factor XII triggering fatty acids such as stearates) and factors XII and VII activation has been suggested.[42, 43] It can be suggested that the three major alterations in hemostatic aspects (factor VII, fibrinogen, and PAI-1), prognostic for cardiovascular diseases, may theoretically be added to syndrome X to create syndrome X+.

These mechanistic links between all alterations related to cardiovascular diseases are too striking to ignore, but apparently the statistical evaluation of the individual factors shows them in many cases to be also independently related to cardiovascular diseases. It may be pertinent to change the scope here and try to identify combination formulas and replace the desire to identify independent risk factors for the desire to understand why mechanistically linked alterations can show statistically independent risks. A possibility for the latter resides in the above-raised possibility that factors can show a combination of being a marker and an aggravating factor and that the degree of reaction to a metabolic change is genetically independently regulated or subject to major polymorphisms.

Individuals at risk. Changes in plasma levels, such as those that can be induced by oral contraceptives, should not be judged according to magnitude only. In addition to large changes, smaller changes are also of importance for persons with a plasma level that is already at the edge of the normal distribution. Even a relatively small change can bring such individuals outside the normal range and will specifically involve components that apparently need a tight regulation of plasma levels. Similarly, even small changes (in the "wrong" direction) in heterozygotes for a deficiency, such as antithrombin III deficiency, can be deleterious for those individuals. In most persons with normal plasma levels, such a small change is generally of no consequence. Thus such quantitatively small changes may be relevant only for a small percentage of the population but nevertheless should be considered. In this respect factors with a strict regulation of plasma levels may be relevant (e.g., antithrombin III).

Another individual risk lies in individually variable combinations of multiple changes. This can be illustrated for oral contraceptive use. Although in oral contraceptive–taking groups as a whole, both "procoagulant" and "profibrinolytic" changes occur and may seem compensatory, in some persons no such compensation was seen.[44] Therefore the use of oral contraceptives may produce individual profiles that are different from the average trend and may either be combined to a shift toward increased risk of thrombosis or toward bleeding complications.[44]

Taking these individual aspects into account, it appears that in theory any change in hemostatic variables, induced by a drug, will place some persons at risk for clinically relevant alterations in hemostasis. It will be important to identify those persons and exclude them or alternatively to develop drugs that induce minimal or no changes in hemostatic variables.

Interestingly, the termination of a drug or even modification of a life-style with an impact on hemostatic variables can give similar effects.

Limitations of laboratory diagnosis of hemostasis

It is most certainly utopic to assume that in the future, all thrombotic and cardiovascular diseases will be predictable or explainable by laboratory diagnosis of hemostasis. In most cases multiple factors contribute in a

complex way, which include individual differences. The present possibility to explain 31% of clearcut familial thrombophilia only by measurable defects in hemostasis (using most available hemostasis assays in 1988[4]) is rather meager. The present predictive power of risk factors is also rather low. We can blame our limited knowledge of hemostasis for that, but it can also be proposed that our limitation in diagnosing the mainly local processes of hemostasis in samples of circulating blood is a crucial factor (Fig. 2). This aspect will be elaborated on and an improvement for the near future will be discussed next.

Local aspects versus systemic measurement. The potential of the hemostatic system is determined by local concentrations of activating, inhibiting, and regulating components that at a particular place become involved in coagulation, platelet action, and fibrinolysis. We can determine the concentration of circulating factors in blood but cannot determine the local situation that involves accumulation of some components on receptors or structures formed during the process, such as fibrin and activated platelet masses, and that involves local cellular reactions of endothelium and platelets.

In recent years it has become clear that local aspects of the hemostatic processes are much more significant than previously thought. The platelet contribution to local coagulation was already well appreciated and includes various more interactions.[45,46] Also notable is the release of large amounts of PAI-1, which can be modulated by the potency of coagulation.[47] The involvement of endothelium has especially become more clear. The following two examples of endothelial involvement in both coagulation and fibrinolysis will illustrate this point.

Endothelium and coagulation and fibrinolysis. The quiescent endothelium contributes to the anticoagulation process by providing the receptor thrombomodulin, which is essential in damping the coagulation cascade by way of protein C. Endothelium further synthesizes the cofactor for protein C action, protein S, and provides a binding site for this protein. Nawroth and Stern[48] have postulated that the endothelium can change its contribution in hemostasis from anticoagulant, which is the condition of the quiescent cell, into procoagulant when the cell becomes perturbed. The perturbed cells start to express tissue factor, and a complete surface-bound process of coagulation with binding sites for factors IXa, VIIIa, X, and Xa is facilitated, which results in the local generation of thrombin. Evidence is provided that this change involves a set of coordinated changes (more than mentioned above), all of which contribute to a shift from anticoagulation to procoagulation.

It is difficult to diagnose the endothelial condition because most components are endothelium bound. One possible circulating marker of the perturbed condition of the endothelial cell that deserves mention is PAI-1, which is made in larger quantities by perturbed cells. PAI-1 is one of the few released factors in this process. It is possible that part of the observed importance of PAI-1, as a prognostic indicator for postoperative thrombosis[49] and recurrent myocardial infarction[22] and its elevation in coronary artery disease,[50-52] signals the presence of perturbed endothelial cells somewhere in the vascular tree.

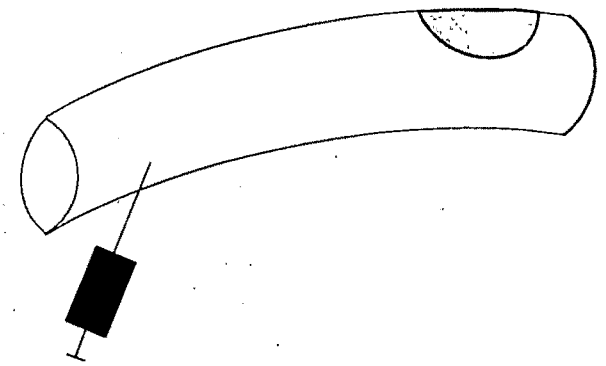

Fig. 2. Cartoon depicting our present practice of analyzing a distantly collected blood sample, whereas hemostatic processes are usually local. Only a limited answer can be expected regarding whether the potential of the system will be adequate in the local process and whether the process at the locus develops appropriately for healing.

An important contribution of endothelium to fibrinolysis is the acute release of t-PA in response to triggers, notably those derived from coagulation and platelet activation. The significance of this acute release is to provide t-PA locally in high concentrations at the right moment. As shown by several studies,[53-55] the presence of t-PA before clot formation results in a much more efficient lysis than does t-PA that is available after the formation of the clot. The timing of the availability of t-PA, relative to fibrin formation, determines the impact of the acutely released t-PA.

The phenomenon of acute release of t-PA suffers from tachyphylaxis.[56, 57] This applies only when the same trigger of the release is repeatedly involved. When other triggers of the acute release are used as a second or subsequent trigger, no tachyphylaxis occurs,[56] which indicates that repeated or chronic stimulation of the endothelium can result temporarily in periods of poor reactivity. At present the capacity of the vessel wall to release t-PA is tested frequently by infusion of desmopressin acetate.[58] This is a systemic test providing data on generalized or large abnormalities.

Future perspectives in laboratory diagnosis of hemostasis. In laboratory diagnosis we must distinguish

between two approaches. The first approach is the study of the potential of the systems by assessment of supply of factors and the functioning of the system by in vivo and in vitro tests. The second approach is the study of the action of the systems as reflected in its reaction products. In particular the assessment of the action of the systems can provide progress in the near future.

The action of the system is marked by the occurrence of several reactions involving release of components from cells, changes in membranes, limited proteolysis, change in functions of proteins, and complex formation. The changes provide new entities, such as split-off peptides or formed enzyme inhibitor complexes, and changes in concentrations of components in the case of reactive synthesis. In blood we can measure the concentration of released reaction products of recent or ongoing action, and we will detect (some of) the effects on cellular release and reactive synthesis. We will not see the components that are and remain tissue bound.

There are increasing opportunities to detect low levels of reaction products of hemostasis activation, including the use of special monoclonal antibodies. It becomes further clear from recent reports that the concept of continuous low-grade turnover in these systems, as originally proposed by Astrup,[2,59] holds true and that analysis of this low-grade action at several levels of the cascades is possible. The first advantage of this approach in laboratory diagnosis is that the level of reaction products indicates the real action in the system. The assay of blood levels of proenzymes, cofactors, and inhibitors only provides us with an estimate of the potential of the system. The effects of the potential and its changes always require interpretation with our knowledge about the system and its mechanisms, and this knowledge is far from complete. Second, the evaluation of reaction products solves part of the problem that hemostatic processes are primarily localized and laboratory diagnosis is limited to the study of systemic blood samples. The reaction products provide information about all local events and indicate whether the locally released or bound factors have had effects. A remaining restriction is that the reaction products only provide an averaged and diluted message and do not provide an answer about the localization of the action. However, this latter aspect might also be advanced further in the future by using techniques of local sampling, sampling at several places, and occlusion of segments.[60,61]

It is advocated to analyze further the effects of the use of drugs such as oral contraceptives by evaluation of not only the changes in variables of the potential of the hemostatic systems, but specifically also changes in the parameters of the action of these systems. Some data on circulating reaction products can be found in these proceedings. The data on the prognostic value of levels of reaction products for thrombotic and cardiovascular diseases are still very limited. An interesting option has been presented by Owen et al.,[62] who showed for the postoperative period that the ratio of reaction products from coagulation and fibrinolysis was increased preceding deep venous thrombosis. This indicates that as proposed by Nossel,[63] ratios of action parameters of coagulation and fibrinolysis may be informative of the balance between the systems and of deviations in the balance.

Interrelations between carbohydrates, lipids, and the hemostatic system in relation to the risk of thrombotic and cardiovascular disease

Irene Juhan-Vague, MD, PhD, and Philippe Vague, MD, PhD
Marseille, France

Metabolic diseases, such as obesity, impaired glucose tolerance, type I and type II diabetes, hypercholesterolemia, and hypertriglyceridemia, are among the main risk factors for the development of atherothrombosis. Various abnormalities of the hemostatic system (platelet hyperaggregability, hypercoagulability, and hypofibrinolysis) have been described in all these situations. The individual effect of each of these diseases on the hemostatic system is difficult to evaluate because these states are often associated in the same patient and the treatment of one can benefit the others. Therefore it may be queried if a common abnormality of these pathologic states might explain their impact on the cardiovascular system. We have been interested by hyperinsulinemia, which is observed in obesity, impaired glucose tolerance, type II diabetes, and hypertriglyceridemia, and we have shown a very strong correlation between plasma insulin, body mass index, triglyceride levels, and one of the main inhibitors of the fibrinolytic system, plasminogen activator inhibitor-1. Partial correlation analysis showed that only the correlation between insulin and plasminogen activator inhibitor-1 was independent. Therefore a high plasma insulin level could be responsible for elevated levels of plasminogen activator inhibitor-1, which by inducing an hypofibrinolysis, could play a role in the deposition of fibrin and the development of atherothrombosis. The description of some interelations between metabolic diseases and hemostasis is satisfactory but does not exclude specific effects of these diseases on hemostasis, such as glycation of the coagulation and fibrinolytic factors in diabetes or toxic action of lipoprotein on endothelial cells in hyperlipoproteinemia. (AM J OBSTET GYNECOL 1990;163:313-5.)

Key words: Insulin, carbohydrate metabolism, lipid disorder, hemostatic system, cardiovascular disease

Carbohydrate and lipid disorders are among the main risk factors for the development of atherothrombosis. Various abnormalities of the hemostatic system have been described in all these disorders and may play a role in the initiation of the atheromatous lesion or its complication. However, the individual effect of each of these metabolic disorders on the hemostatic system is difficult to evaluate because these states are often associated in the same patient and the treatment of one can benefit the others.

Carbohydrate and lipid disorders are among the main risk factors for the development of atherothrombosis

Disorders of the glucose metabolism include mainly types I and II diabetes and impaired glucose tolerance and may be extended to increased calories storage, that is, obesity, especially when the fat distribution is oriented through the upper part of the body (abdominal or android obesity) and also to other insulin-resistant situations, the importance of which is now well recognized. Lipid disorders include increased plasma concentrations of triglycerides and low-density lipoprotein (LDL) cholesterol, which is often accompanied by a concomittant absolute or relative decrease in high-density lipoprotein cholesterol.

Various abnormalities of the hemostatis system have been described in all these situations.

Carbohydrate disorders are accompanied by platelet hyperactivity, with an increase in plasma von Willebrand factor, hypercoagulability with increased fibrinogen and factor VII level,[1] and hypofibrinolysis with increased plasma concentration of plasminogen activator inhibitor-1 (PAI-1).[2] At the vessel wall level, a proliferation of smooth muscle cells, an increase in lipid synthesis and deposition, a thickening of the basement membrane, and glycation of collagen have been reported.[3] Admittedly, these abnormalities are mainly due to the effects of hyperglycemia and advanced glycated end products[3] on the one hand and to the effects of hyperinsulinemia on the other.[4]

Lipid disorders are also accompanied by platelet hy-

6/0/17879

peractivity, hypercoagulability with increased factor VII,[5] and hypofibrinolysis with increased PAI-1.[6, 7] At the vessel wall level, an accumulation of lipid-filled foam cells is found.[8] The role of increased LDL cholesterol and apolipoprotein B, as well as the decrease in HDL cholesterol and apolipoprotein A_1, is now well established, and the toxic effect of oxydated lipoprotein on endothelial cells has been demonstrated.

Carbohydrate and lipid disorders are very often associated in the same patient and the treatment of one of them can benefit the others

More and more importance is presently given to abnormalities in insulin action and secretion. Reaven[9] proposed that insulin resistance is the common cause of several abnormalities, which he grouped under the term "syndrome X," and which includes the following: (1) android obesity, hyperinsulinemia, impaired glucose tolerance, and type II diabetes; (2) increased triglyceride and very low–density lipoprotein, increased LDL cholesterol, and decreased HDL cholesterol; and (3) hypertension.

Several intervention programs are able to decrease insulin level, such as diet in overweight persons, which improves glucose uptake by the periphery, an exercise training program that increases the number of insulin receptors, and antidiabetic drugs, such as biguanides, which improve insulin sensitivity. All these interventions[10, 11] can in parallel decrease more or less insulin, triglycerides, and LDL cholesterol, and increase HDL cholesterol.

Some interrelations exist between carbohydrate, lipid, and hemostatic disorders

Hypofibrinolysis favors the deposit of intravascular fibrin. Fibrinolysis is regulated through activators and especially inhibitors, the main one of which is PAI-1.[12] The plasma level of this inhibitor appears to be an independent risk factor for myocardial reinfarction in previously infarcted men <45 years old.[13]

It has been shown that plasma concentration of PAI-1 is increased in these patients[14-16] and patients with hypertriglyeridemia.[6, 7] We have also recently observed a close relationship between low fibrinolytic activity, high PAI-1, and high fasting plasma insulin levels in various populations: normal subjects,[14] premenopausal obese women,[15, 16] noninsulin-dependent diabetic subjects,[17] and patients with angina pectoris.[18] In all these studies the independent correlation coefficient between PAI-1 and insulin was around 0.6. Partial correlation analysis showed that triglyceride level or body mass index was no longer correlated with PAI-1 level after adjustment for insulin.

Furthermore, interventions to reduce plasma insulin level (and resistance), such as fasting[14, 19] or metformin administration,[11] induced a decrease in PAI-1 level. The hypothesis that insulin level regulates PAI-1 level is supported by the fact that insulin stimulates PAI-1 synthesis by liver cells in vitro.[20] Therefore high plasma insulin levels could be responsible, through direct action on liver synthesis, for elevated plasma triglyceride and PAI-1 levels. By inducing hypofibrinolysis, the latter could contribute to the pathogenic role of hyperinsulinemia. The normalization of insulin levels can be accompanied by the normalization of the lipid pattern and also PAI-1 level, that is, the suppression of one of the main hemostatic risk markers for myocardial infarction.[18]

Carbohydrate and lipid disorders also have specific effects on hemostasis and vessel wall

The description of some interrelations between metabolic diseases and hemostasis is satisfactory but does not exclude the specific effect of these diseases on hemostasis. In diabetes, glycation of proteins is an important pathogenic phenomenon. The glycation of hemostasis factors decreases their activity, that of LDL renders them more pathogenic and potentiates lipid accumulation in vessel wall, and that of collagen and basement membrane increases the trapping on von Willebrand factor, which favors platelet adhesion.[3] In lipid disorders, it is observed that oxydated LDL has a toxic effect on endothelial cells.[8]

In conclusion, both hyperglycemia and hyperlipoproteinemia per se modify the hemostatic milieu favoring the development and clinical complications of atherothrombosis. However, carbohydrate and lipid disorders are frequently associated, one leading to a potentiation of their impact on the vessel wall. Furthermore some abnormalities commonly observed in both these types of disorders, especially insulin resistance and excess, may explain the association of carbohydrate and lipid disorders as risk factors for atherothrombosis in epidemiologic studies.

Why do we need pharmacokinetic studies?

Eigill F. Hvidberg, MD
Copenhagen, Denmark,

Data on the fate of sex steroids in the human organism, such as absorption, distribution, total clearance, and elimination routes, are necessary to understand and predict drug action. However, except for a few exceptions, such data are sparsely available. It is necessary to apply several approaches (descriptive, mathematic, and analytic) to describe variability and dose-response correlations, all of which are important for individualized treatment, and therefore of therapeutic relevance. In addition, such data are now unavoidable requirements for the evaluation of safety, efficacy, and quality performed by the regulatory authorities. Therefore human kinetic information is an integral part of the knowledge that forms the basis for any treatment with sex steroids. (Am J Obstet Gynecol 1990;163:316-8.)

Key words: Pharmacokinetics, dose response, variability, sex steroids

The question, "Why do we need pharmacokinetic studies?," is not easily answered whether it concerns sex steroids or any other preparation, and particularly not if seen in a clinical context. However, to address the problem in general, it is necessary to discuss some details of the pharmacokinetic universe.

Definition

While pharmacodynamics are characterized as the action of a drug in the organism, pharmacokinetics deal with the fate of a drug. However, a more operational description of pharmacokinetics is all the processes that determine the concentration of the active substance at the receptor site. This definition implies the connection with pharmacodynamics, without which kinetics may easily develop into a nonclinical playground.

Study approach

To obtain the kinetic characteristics of a drug, several types of studies are needed. The usually overlapping approaches may be classified into the following three basic ones: (1) *The descriptive approach,* by which all the processes involved are described, for example, how the absorption, distribution, and elimination take place and how the different organs and physiologic conditions influence these processes; (2) *the mathematic approach,* which includes calculations of compartments and rate constants, generation of models, and other types of "pharmacomathematic" exercise; and (3) *the analytic approach,* which tries to analyze the generated data in the context of other pharmacologic and clinical information.

The unifying concept is to explain and predict drug action in the human body. All three approaches are based on the measurements of concentrations in body fluids of the parent compound and its metabolites, most often by establishing plasma concentration/time curves. Therefore the value of such studies is heavily dependent on analytic assays that require a high degree of sensitivity, reproducibility, and specificity.

Parameters and data

Much uncertainty seems to exist about which pharmacokinetic parameters are essential. Table I shows what generally is required, but for more information, recent handbooks must be consulted.[1]

It would be of interest to see how much kinetic data on sex steroids are actually available in the literature. In most recent source of such information,[2] data on clearance, T½, V_d, and protein binding are given for only ethinyl estradiol, levonorgestrel, medroxyprogesterone acetate, and norethisterone. Even in the original kinetic studies, little data exist, at least compared with other groups of drugs. The paucity of information is striking.

Variability

Pharmacokinetic data are usually presented as an average of results from a studied population.[3-5] Naturally, such general information is important for the common characterization of the drug in question but cannot be used to predict, for example, plasma concentrations in individual patients. A range is often of greater interest

From the Department of Clinical Pharmacology, University Hospital (Rigshospitalet).
Reprints not available.
6/0/18222

than a mean value, and kinetic data should therefore include information on the variability between individuals.

For most drugs, the variability in kinetic parameters is more than 10-fold, even if the study population is quite homogenous and the dose is corrected for body weight. Basically, this can originate from variability in absorption and from differences in the metabolizing capacity of the liver caused by genetic or environmental factors. Presystemic metabolism seems to be an important determinant for the plasma levels of progesterone.[6] On the basis of individual kinetic data, it may be possible to sort out such factors. In addition, intraindividual variability might be large (see Fotherby, this supplement).

The dose-response concept

As emphasized, kinetic data only have a meaning when related to pharmacodynamic data. The pharmacologic way of expressing this is by dose-response curves, in which the dose may be substituted by plasma concentrations or other kinetic parameters. To generate meaningful and relevant concentration-response curves in patients is an extremely difficult task and therefore often neglected. However, if the concept became better understood, more energy would be put into this work. For sex steroids, only a few, if any, such human dose-response curves exist. This is also related to the difficulty in grading the effect parameter, although this may be overcome by the use of the percentage of "failures/successes" related to plasma concentration. However, both measuring and grading the effects are still the main obstacles for setting up reliable dose-response curves,[7, 8] and very sparse kinetic information makes this even more problematic. Another important use of dose-response curves is that they are necessary for meaningful comparisons between analogous drugs.

Regulatory requirements

The basic idea in drug regulation is that only drugs for which safety, efficacy, and quality have been evaluated—and found acceptable—are released for general use. The requirements should, of course, reflect profesional thinking and clinical relevance. Kinetic information must be presented for the evaluation of both safety and efficacy, because it will be required for most drugs to estimate toxic plasma concentrations and minimum plasma levels for efficacy. This means that kinetic studies should not be limited to healthy volunteers but be extended to relevant patient categories including risk groups, such as renal and hepatic insufficiency, and old age.

Today drug regulation is increasingly involving demands on the conduct of clinical trials. In Europe rules for good clinical (research) practice—the so-called Good Clinical Practice rules—will be the foundation of the authorities' future demands regarding trials of new drugs,[9] as in the United States.

Table I. Pharmacokinetic parameters required

Characteristics	*Parameter*
Absorption:	Absorption fraction (F), T_{max}, C_{max}
Distribution:	V_d, protein binding
Elimination:	Route, $T^1/_{2\beta}$, Cl_{tot}, pattern of metabolites, saturation phenomena
Steady-state:	Area under the curve (e.g., $AUC_{24\ hr}$), therapeutic plasma concentration range
Special features:	Kinetic interactions, influence of hepatic/renal insufficiency and age, autoinduction, and active metabolites

Therapeutic relevance

As previously stated, it should also be possible to use data from pharmacokinetic studies in humans as a prognostic instrument. Without this objective, pharmacokientics may be reduced to a sophisticated, academic exercise and, therefore, ethically questionable. Only a few examples within sex steroids exist, but to demonstrate the concept of the beneficial use of plasma concentrations, an example from cytostatics will be given. Methotrexate plasma levels were used to predict therapeutic outcome,[10] and it was found that patients with levels above a discriminating limit had a much greater chance of remission despite the fact that the same dose was given. This can, of course, be developed into a regular therapeutic drug monitoring system, but even without it, this line of thinking could be applied to existing data on sex steroids.[5] Therefore it would be a reasonable question whether such data could be used as a predictor of therapeutic outcome. Some efforts have been made in the treatment of breast cancer with medroxyprogesterone.[11] Furthermore, some data for prophylactic treatment of osteoporosis[12] may eventually be used in this connection. Finally, the induction of estrogen metabolism by phenobarbital or rifampicin should be better investigated in terms of kinetic data to define special risk groups, that is, those who lose the contraceptive effect because of this drug interaction.

In conclusion, the response to the question, "Why do we need pharmacokinetic studies?" is as follows: (1) A general characterization of the drug in humans includes kinetic information. (2) An estimation of the kinetic contribution to the variability of drug response is essential both between and within individuals. (3) Meaningful dose-response curves must be based on pharmacokinetics to design optimal dose regimens and to compare analogous drugs. (4) Regulatory authorities require kinetic data for a thorough evaluation of safety,

efficacy, and quality. (5) General measures may be developed on basis of kinetic studies to predict the outcome of a given drug treatment in individual patients on a safer basis. (6) Finally, sex steroids constitute no exception to these requirements.

Selected aspects of the pharmacokinetics and metabolism of ethinyl estrogens and their clinical implications

Joseph W. Goldzieher, MD
Houston, Texas

Careful studies in an adequate sample of subjects show a very marked degree of variability in the pharmacokinetics of ethinyl estradiol—specifically, in parameters such as area under the curve, half-life, and time to peak. This variability is seen in differences between different populations, as well as from one individual to another. These studies also show variability in area under the curve and other parameters in the same person from time to time. Such differences may equal or exceed the differences between low dose (35 μg) and high-dose (50 μg) formulations. The levels of plasma ethinyl estradiol produced by a 50 μg dose of mestranol are similar to those from 35 μg of ethinyl estradiol. Thus a high-dose pill may be no higher than a low-dose pill if the nature of the estrogen is not kept in mind. Qualitative differences in the oxidative metabolites of estrogens may be of significance with respect to oncogenic potential. (Am J Obstet Gynecol 1990;163:318-22.)

Key words: Ethinyl estrogens, area under the curve, mestranol, ethinyl estradiol, pharmacokinetics

Although the pharmacokinetics of ethinyl estrogens have been studied intensively for more than a decade,[1] many unresolved problems of practical interest, as they affect contraceptive effectiveness, remain to be examined.

Population differences

It has been established by the work of Fotherby et al.,[2] Goldzieher et al.,[3] and others that the pharmacokinetics of ethinyl estrogen, particularly blood levels and consequent area under the curve, differ from one population to another despite correction for body weight. The origin of these differences, whether they are caused by dietary, ethnic, or other factors, is unknown. They are not, however, merely differences in rates of gastric absorption or renal excretion. Studies comparing women in Nigeria, Sri Lanka, and the United States have shown that the pattern of steroid conjugation to sulfates and glucuronides, which is primarily a hepatic function, varies from one locality to another.[4] Moreover, analysis of urinary steroids shows qualitative and quantitative differences in oxidation of the steroid molecule at the 2, 6, and 16 positions. The origin of these differences in enzymatic attack on the steroid molecule has not been investigated except to show that they are present on initial exposure of the subject to these agents and remain essentially unchanged after many months of contraceptive use.

Circulating ethinyl estrogen sulfates

The sulfates of estrogens circulate in the blood in much higher concentration than the free steroid itself, often by an order of magnitude. Studies in baboons have examined the kinetics of the ethinyl estradiol sulfates[5]; more recently the kinetics and bioavailability of the 3- and 17-sulfates have been examined in human volunteers.[6] The statistics of interest are shown in Table I. The half-lives of both conjugates are not appreciably different from the half-life of ethinyl estradiol itself; consequently, the notion that these sulfates persist for long periods and act as a potential reservoir for the regeneration of free ethinyl estradiol cannot be maintained. Although the two sulfates show large differences in area under the curve and bioavailability, the most significant finding of practical interest is the rate of conversion to free, circulating ethinyl estradiol. After oral administration of the 3-sulfate, only about 20% appears as free ethinyl estradiol in the blood; the 17-sulfate produces about half this amount. This does not augur for a clinically important role that might help "tide over" spells of low plasma ethinyl estradiol levels resulting from noncompliance.

We have also observed that individual variation in plasma total ethinyl estradiol sulfate levels shows the same large spread as has been observed by many investigators for free ethinyl estradiol. This is true for the conjugates resulting from the oral administration of the 3- or the 17-sulfate.[7]

Bioavailability

Although it is tempting to assume that preparations of similar hormone content made by various major manufacturers are identical in bioavailability, the published comparative data are very scanty. We have recently analyzed the pharmacokinetics of three 1 mg norethindrone/35 μg ethinyl estradiol and three 1 mg norethindrone/50 μg mestranol formulations; these data have been published.[6] Comparisons of plasma level data for the three ethinyl estradiol preparations show that they are indistinguishable based on mean values, standard deviations, and highest and lowest individual plasma patterns. The three mestranol-containing agents are equally similar, and there are no statistically significant differences in area under the curve.

Conversion of mestranol to ethinyl estradiol

Of great interest was a comparison of ethinyl estrogen levels obtained from the administration of 50 μg of mestranol compared with the direct administration of 35 μg of ethinyl estradiol. This issue of conversion of mestranol to ethinyl estradiol has been discussed repeatedly in the literature and has often been obfuscated by reference to the interconversion in rodents, which is quite different from that in humans. In any event, the administration of 50 μg of mestranol resulted in an average area under the $curve_{EE}$ of 963 ± 544, whereas that from 35 μg of ethinyl estradiol produced an area under the curve of 1036 ± 483 (Table II). In

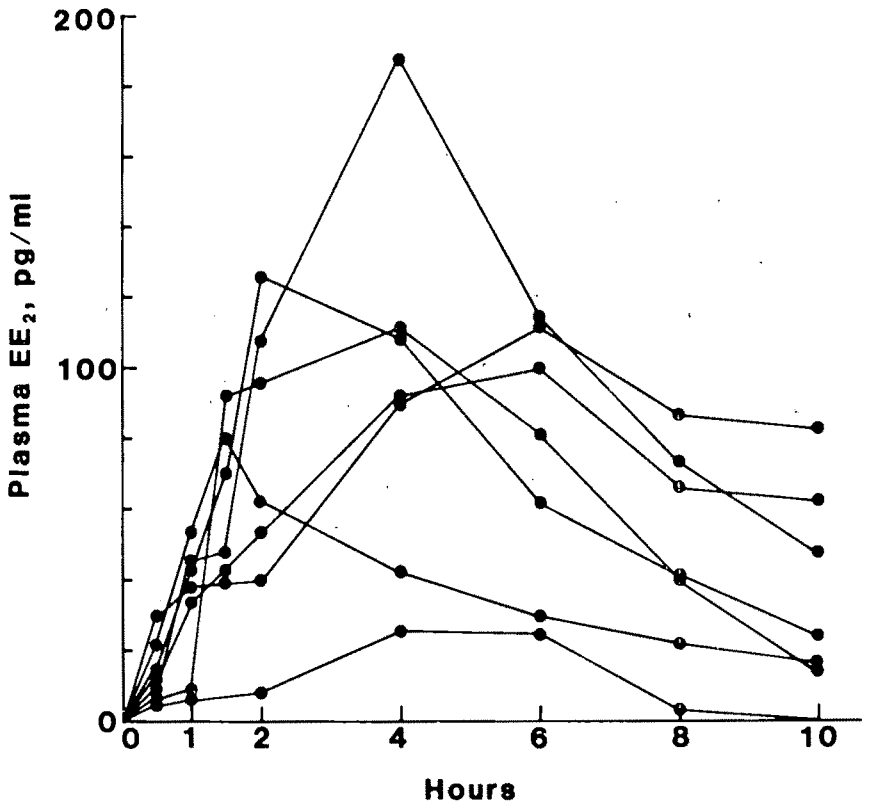

Fig. 1. Plasma ethinyl estradiol levels after single-dose administration. The great variability, despite efforts to eliminate external variables, is noteworthy. (From Goldzieher JW. Pharmacology of contraceptive steroids: a brief review. AM J OBSTET GYNECOL 1989;160:1260-4.)

Table III. Intraindividual variability (three single-dose trials)

	CV (%)	*Range (%)*
Norethindrone		
1/35	17.4	−79 → +134
1/50	36.5	
Ethinyl estradiol		
1/35	41.0	−7 → +92
1/50	42.0

CV, Coefficient of variation.

other words, 35 μg of ethinyl estradiol is a "stronger dose" than is 50 μg of mestranol. In truth, the difference is not statistically significant because of the extremely wide range of interindividual variation. However, epidemiologic comparisons of 50 μg oral contraceptives with "low-dose" 35 μg oral contraceptives are meaningless unless the estrogens are kept straight.

Inter- and intraindividual variability

Interindividual variability has often been documented but seldom quantitated in sufficiently large groups. In the study of Brody et al.,[6] 24 patients received the 35 μg ethinyl estradiol formulations and 27 received the 50 μg mestranol agents. The details of interindividual variation are shown in Table II in standard deviation, coefficient of variation, and extreme range of values. Similar results have been previously published for ethinyl estradiol (Fig. 1) and ethinyl estradiol sulfates (Fig. 2). Norethindrone (Table II) shows comparable findings as might be expected because it also undergoes enterohepatic recycling.

The study of Brody et al.,[6] which examined the pharmacokinetics of three identical formulations by different manufacturers, showed them to be bioequivalent. This observation permitted an insight into intraindividual variation, since all three brands were tested in each individual, at the same time of the cycle, in three consecutive months. Only a single dose was administered in each cycle. There are virtually no published data on intraindividual variation, and the extreme degree of variability came as a considerable surprise. The ranges and coefficients of variation are given in Table III and individual examples in Table IV. Extreme values ranged from −79% to +134% of the mean of the three determinations per individual.

The findings of such a range of inter- and intraindividual variability have important clinical implications. It is quite clear that plasma ethinyl estradiol levels

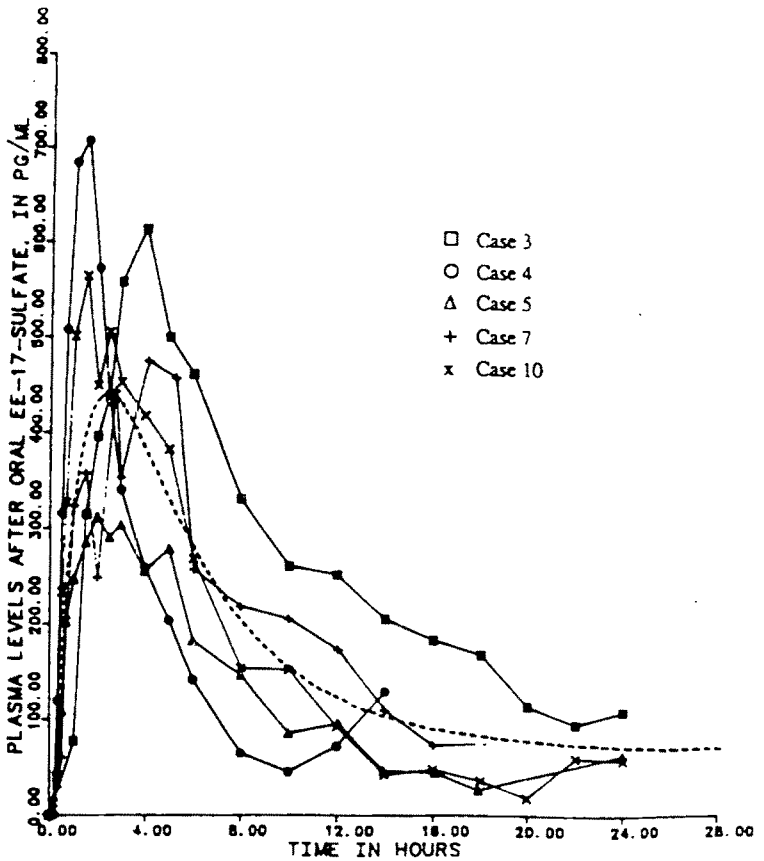

Fig. 2. Plasma levels of ethinyl estradiol after single-dose oral administration of ethinyl estradiol 17-sulfate in five individuals. *Dotted line* represents mean value. (From Goldzieher JW, et al. Human pharmacokinetics of ethynyl estradiol-3-sulfate and 17-sulfate. Steroids 1988;51:63-79.)

EE, Ethinyl estradiol; *ME*, mestranol.

engendered by 35 μg ethinyl estradiol may be indistinguishable from those produced by 50 μg in another person; thus these gravimetric values give a false sense of dosage discrimination. This accounts for the well-established observation that the same dose may produce overdosage effects (e.g. nausea) in one person and underdosage effects (e.g. breakthrough bleeding) in another. It also points out that efforts at fine-tuning dosage to minimize adverse effects of either variety are not going to succeed except "on the average." Finally, comparisons of the effects of one dose with another will have to take account of a broad degree of overlapping if the effects in question are related to the plasma kinetics of the compound.

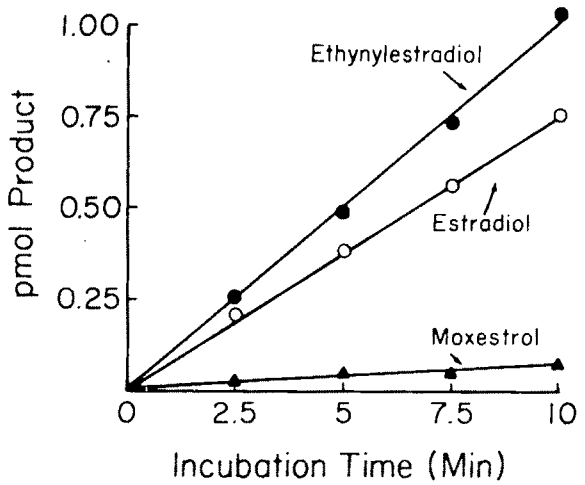

Fig. 3. Concentration of oxidative metabolites of various ethinyl estrogens after incubation with a cell population in vitro. (From Purdy RH, Goldzieher JW. Intervention in the aging process, part A. Qualitative, epidermiology and clinical research. New York: Alan R Liss, 1983:247.)

Qualitative differences in ethinyl estrogens

Finally, I will comment on qualitative differences in the ethinyl estrogens over and above the question of the metabolic conversion of mestranol to ethinyl estradiol. Another compound, moxestrol, the 11β-methoxy derivative of ethinyl estradiol, is available in some countries. It is approximately 10 times as potent as ethinyl estradiol itself, which means that 2 to 3 μg, together with a progestin, should be contraceptively effective. However, this is merely a question of relative potency. What is the most interesting feature of this compound is its activity (or rather inactivity) in promoting neoplastic transformation of certain cell clones. These data have been published[8] but have not been widely recognized for their importance. Briefly, exposure of certain cell clones to estradiol, ethinyl estradiol, stilbestrol, etc., causes formation in vitro of foci of transformed (neoplastic) cells, as shown in Table V. Moxestrol, although estrogenically active, did not produce cell transformation. The mechanism of this effect has been elucidated.[9] All the estrogens that can produce this neoplastic transformation can be oxidized to catechols or epoxides, structures that are known to play a role in the carcinogenic effects of polycyclic hydrocarbons. As shown in Fig. 3, the incubation conditions used produced linear increases in these oxidative metabolites with estradiol or ethinyl estradiol but not with moxestrol. The 11β-methoxy group appears to interfere with this type of oxidative attack. One cannot, of course, extrapolate from this effect to the oncogenic role of estrogens in humans, but it assuredly opens a new avenue of exploration for the development of potentially "safer" estrogens.

Table V. Neoplastic transformation of Balb/c 3T3 A-31-1-13 subclone by estrogens

Chemical	*Concentration*	*Total type III transformed Foci on ___ of ___ dishes*
DMSO control	0.25%	0 on 0 of 15

Pharmacokinetics of gestagens: Some problems

K. Fotherby, PhD
London, England

Various approaches to studying the pharmacokinetics of gestagens and the factors that influence derivation of the parameters are described with levonorgestrel used as an example. Published studies of the pharmacokinetics of levonorgestrel are reviewed, and new information is presented regarding intra- and intersubject variation. Differences between various formulations of levonorgestrel are apparent when the formulations are compared in the same subjects. There is also a marked difference in the parameters when derived under single-dose or steady-state conditions. The role of sex hormone–binding globulin in the metabolism of levonorgestrel is questioned. Large intra- and inter-subject variations in the parameters exist, and a subject may show a large month-to-month variation when one levonorgestrel formulation is used and smaller variations when another formulation is used. This wide variability in the pharmacokinetic parameters, problems that arise in the derivation and interpretation of the parameters, the biologic significance of most of these parameters, and their lack of correlation with pharmacodynamic responses severely limit the usefulness of pharmacokinetic studies of the gestagens. (AM J OBSTET GYNECOL 1990;163:323-8.)

Key words: Pharmacokinetics, gestagens, oral contraceptives, variability, sex hormone–binding globulin

The comments on pharmacokinetics presented in this article relate only to the gestagens used in oral contraceptives. The pharmacokinetics of contraceptive steroids is a specialized topic, as evidenced by the fact that most textbooks and monographs on pharmacology denote little if any attention to this area. The pharmacokinetics of the gestagens show many facets not seen with most other drugs, and these lead to many problems in both the derivation and interpretation of the pharmacokinetic parameters.

There are four main approaches to the pharmacokinetic analysis of serum drug concentrations: (1) Simple description describes the changes in serum drug concentrations with time and allows the determination of the rate of absorption and bioavailability, the rate of elimination of the drug, and the steady-state concentrations. (2) Compartment modeling derives equations based on the assumption of one, two, or more body compartments throughout which the drug is distributed and relates changes in serum drug concentrations with time. The assumed compartments may have no physiologic meaning, and as the number of postulated compartments increases, the mathematic complexity increases so that a model based on more than two compartments becomes difficult to deal with. (3) Iterative curve fitting makes no assumptions about compartments, but by computer analysis attempts to derive the equation that best describes the changes in serum drug concentrations with time. Such equations will usually be complex and may be difficult to interpret. (4) Systems dynamics considers the body as a system with a large number of subsystems; the flux of the drug through the various subsystems is determined by positive feedback.[1] This approach has not yet been widely applied and not at all so far to steroids.

Each approach has it advantages and disadvantages and that most appropriate for the problem under investigation must be chosen. Compartment modeling, which uses a two-compartment open model, has been widely used for the gestagens, but the simple descriptive approach will give the clinician, although maybe not the pharmacologist, most of the information required. This information will usually be as follows: (1) how rapidly the gestagen is absorbed (the time required [T_{max}] to reach peak concentration in blood); (2) an indication of bioavailability, usually by assessment of the area under the serum concentration–time curve (AUC); (3) how rapidly the gestagen is eliminated from the body, usually by determining the half-life of elimination; this widely used parameter (the time required for the serum gestagen concentration to decrease by 50%) may, however, often be misleading because it is determined by two other parameters, the apparent volume of distribution and clearance, and these may change considerably, denoting marked changes in the metabolism of the gestagen without any changes in the half-life of elimination. (This aspect is discussed in more detail in a forthcoming article.[2]) However, the

half-life of elimination has the advantage that it can be determined simply from the plot of serum gestagen concentrations against time; (4) the serum concentration under steady-state conditions, since this will be more relevant to the biologic activity of the gestagen than concentrations after a single dose. However, regarding the gestagens, steady-state conditions have not often been determined until recently.

Since these four parameters are the most often derived and useful ones, the factors influencing their determination and interpretation should be considered. Little difficulty usually arises in T_{max} and steady-state conditions so that only half-life of elimination and AUC will be discussed in more detail.

General considerations

Of the gestagens widely used in oral contraceptive formulations, levonorgestrel (LNG) will be mainly used as the example because it has the following advantages: (1) More information is available for LNG than for the other gestagens; (2) it does not undergo a first-pass effect so that complications that may arise as a result of metabolism in the gut or liver are avoided; and (3) most published studies have analyzed their data in a similar way in a two-compartment open model. One disadvantage, but one that is common to the other gestagens, is that most of the pharmacokinetic studies reported have involved only small numbers of subjects. Of the more than 17 papers concerned with serum LNG concentrations after administration of various oral contraceptives containing LNG, only two provide data for more than 10 study periods. Goebelsmann et al.[3] studied 24 women, and although only six were investigated by Dennerstein et al.,[4] sampling was performed during each of 3 months of treatment so that 18 sets of data were available per formulation used. All other studies include less than 10 and usually five or less subjects. Most studies have analyzed the data in a two-compartment open model. Although LNG has been used for illustrative purposes, the points considered are equally applicable to all other gestagens used in contraceptive formulations.

In determining half-life of elimination and AUC, factors that may need to be taken into account include the following: (1) the dose of the gestagen and the route by which it is administered; (2) the dose, if any, of estrogen with which it is administered; (3) the status of the subjects at the time blood sampling is performed; (4) the number of samples and the time period over which they are taken; (5) whether taken under steady-state or single dose conditions; (6) the procedures used for calculating the pharmacokinetic parameters; and (7) the reliability criteria of the method used to estimate the serum gestagen concentrations; this is particularly important with the low-dose formulations at the longer times after dosing since by 24 hours, serum concentrations in many subjects will be near the limit of sensitivity of the assay. This is important not only for the validity of the 24-hour concentration but also for determining whether this concentration is significantly different from that of samples taken later.

In almost all of the studies, sampling has not continued beyond 24 hours, and this may lead to an underestimate of half-life of elimination, particularly for gestagens with a long half-life of elimination (20 hours or more). In such studies half-life of elimination will include the "β-half life" but not the subsequent half-lives of compounds that do not follow the kinetics of a first-order reaction. Similarly, considerable errors may be encountered in determining the AUC. If sampling is terminated at 24 hours, AUC (0 to 24 hours) can be calculated by the trapezoid rule, but AUC (24 to ∞) may be significant for gestagens with a long half-life, and calculation of AUC (0 to ∞) by some suitable equation usually assumes, possibly erroneously, that the elimination rate for the period 24 hours to infinity does not differ from that for 0 to 24 hours.

Elimination of LNG

Published values for half-life of elimination of LNG are summarized in Table I. Most of the reported mean values are within a narrow range, although in three studies[3, 5, 6] considerably longer values were obtained. In one of these studies[3] the longer mean value may result from the larger number of subjects studied and consequently the larger range obtained; this range en-

LNG 750	*LNG 150, EE 30*	*LNG 250*	*LNG 250*	*LNG 250, EE 50*

compasses the values found in all other studies except that of Dennerstein et al.[4] The fivefold range for half-life of elimination shown in Table I agrees with the large variation reported for half-life of elimination of norethisterone,[7] and such a large variation appears to be a common finding with contraceptive steroids.[8] The longer values reported by Humpel et al.[5, 6] are more difficult to explain but they agree with the values calculated from data reported in Dennerstein et al.[4] In this latter study, six women were given either 250 μg LNG or 250 μg LNG with 50 μg ethinylestradiol (EE) daily for 3 months with blood samples being taken at 2, 8, and 26 hours after dosing on the last day of each treatment period. The subjects were randomized to the initial treatment and crossed-over after 3 months of use. From the serum LNG concentrations in the 8 and 26 hour samples, the approximate half-life of elimination was calculated. As shown in Table I, recalculation of half-life of elimination from published studies on the basis of the 8- and 24-hour serum concentrations gave values that, with the exception of two studies,[5, 6] were in good agreement with, although slightly higher than, values obtained from the investigators' pharmacokinetic analyses. Therefore the values calculated from the concentrations reported by Dennerstein et al.[4] appear to be valid. The values for each treatment month for each subject are shown in Table II.

In contrast with the other studies, the values in Table II provide information on half-life of elimination under steady-state conditions and within-subject variability. For some subjects (e.g., subjects 1 and 4, LNG 250 + EE 50; subjects 2 and 5, LNG 250) monthly variations were small, whereas for others (e.g., subjects 2 and 6, LNG 250 + EE 50: subjects 3 and 6, LNG 250) the variation was much wider. The mean intersubject variation was higher (47%) in women receiving LNG 250 + EE 50 than in women receiving LNG 250 (32%), but because of the wide range of these values, the differences would not be statistically significant. It is also of interest and importance that subjects may show a high variability when receiving one formulation and not when receiving the other (e.g., subjects 2 and 5). The intersubject variability for half-life of elimination in this study under steady-state conditions (two-

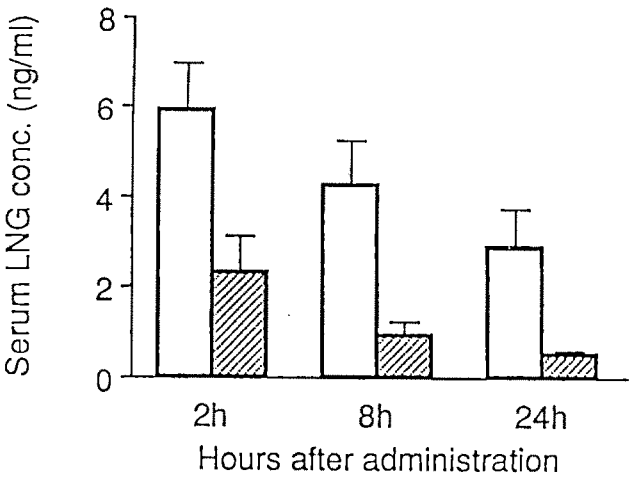

Fig. 1. Serum LNG concentrations in two groups each of six women receiving LNG formulations daily for 21 days □, Women receiving LNG 250 + EE 50; ▨, women receiving LNG 250. Values are the mean; *vertical lines* denote SD. (Data from Dennerstein et al.[4])

to threefold) is probably slightly lower than that observed in single-dose studies.

Bioavailability of LNG

Published values for bioavailability as measured by AUC are summarized in Table III. These values must be related to the dose of LNG, and when this is taken into account, there is reasonably good agreement between the mean values. However, the intersubject variability as shown by the values for SD and the range is high, particularly so in one study.[3] There is also wide intersubject variation with norethisterone,[7] and such large variations seem common to all contraceptive steroids.[8] The recalculated values in Table III refer to determinations of AUC based on serum LNG concentrations at 2, 8, and 24 hours published in the various studies and are calculated for comparison with values similarly obtained from serum concentrations at 2, 8, and 26 hours reported by Dennerstein et al. For most of the studies, this recalculated value is about 75% of the value obtained in the investigators' pharmacokinetic analysis. Therefore the calculation of AUC from the concentrations reported by Dennerstein et al. appears to have some validity. The values for each treatment month for each subject are shown in Table IV.

These values provide information on AUC under steady-state conditions and on within-subject variability. As for half-life of elimination, some subjects show only small month-to-month variations, whereas for others, this variability is much larger. The mean intrasubject variation was generally low (13.8%) in women receiving LNG 250 + EE 50 and significantly lower than that in women using LNG 250 (45.3%). The mean value for LNG 250 + EE 50 in this study (99.7%) is much higher

Table II. Half-life of elimination (hour) of LNG in a group of six women during each of 3 months of treatment with LNG, 250 μg + EE, 50 μg, or LNG, 250 μg, without estrogen (variation percent denotes percent variation of monthly values in relation to subject's mean value, variation ratio denotes highest monthly value divided by lowest monthly value)

than that (36.2%) found by others[9]; this is probably because compared with the latter value the former is obtained under steady-state conditions. Also, again probably because the values in Table IV are obtained under steady-state conditions, the intersubject variation was lower than that seen in single-dose studies.

Role of sex hormone–binding globulin in LNG pharmacokinetics

LNG is known to bind to sex hormone–binding globulin (SHBG) with a greater affinity than other gestagens, and about 50% of the LNG in serum is bound to this protein.[2] The SHBG concentration in serum can be greatly increased by estrogen administration, and in several studies the higher levels of LNG in serum when the gestagen is given with estrogen compared with those when the same dose of LNG is given without estrogen have been attributed to binding of LNG to the increased levels of SHBG.[4, 11, 14] Examples of this phenomenon are shown in Figs. 1 and 2. In Fig. 2 it will also be noted that about 8 days are required to achieve steady-state levels of LNG. The mean value for half-life of elimination from the studies shown in Table I is 15 hours so that steady-state levels of LNG should have been attained in about 3 days. The rise in SHBG concentrations induced by estrogen occurs gradually from the first day of dosing until about day 10 when a plateau is reached,[15] and this has been used as further evidence that the slow attainment of steady-state levels of LNG is associated with the rise in serum SHBG concentrations. However, these suppositions appear untenable. Four studies of changes in serum

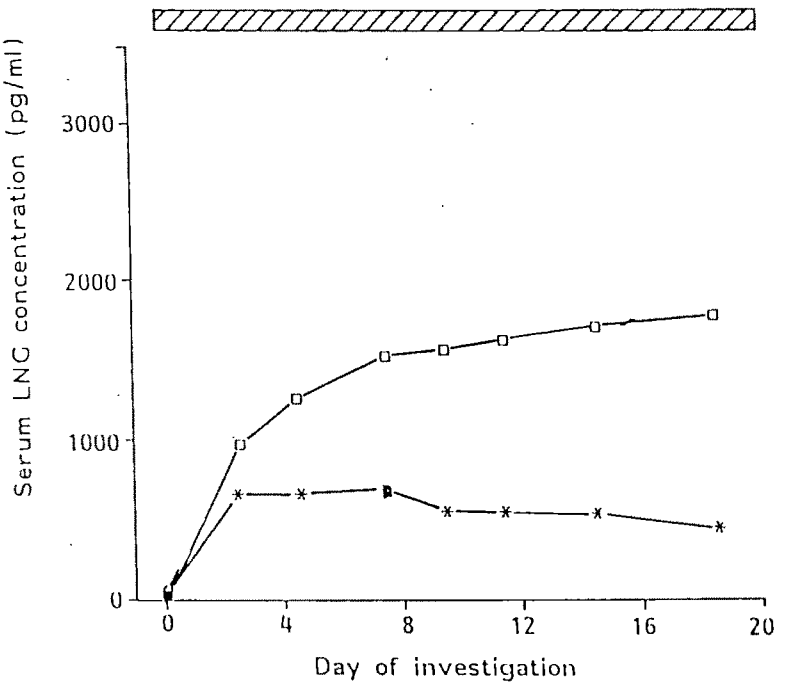

Fig. 2. Mean serum LNG concentrations in two groups each of six women receiving LNG formulations daily for 20 days □, Women receiving LNG 150 + EE 30; *asterisk*, women receiving LNG 150. (Data from Song Si et al.[15])

SHBG concentrations in women taking LNG 250 + EE 50 show *decreases* of from −8% to −36%, with a mean decrease of 24%. These small decreases are unlikely to be statistically significant, but they clearly demonstrate that there is no *increase* in SHBG levels with this formulation. At least 17 studies with LNG 150 + EE 30 report changes in SHBG varying from 0% to 75%. In those studies in which only a small increase was reported, this is unlikely to be statistically significant, but assuming that it is, the mean change in SHBG is a mere increase of 12%. Therefore the mechanisms responsible for the increase in serum LNG concentrations when the gestagen is administered with estrogen to values higher than those when the same dose is administered without estrogen must be independent of SHBG.

In conclusion, this article presents new information on the pharmacokinetics of LNG and provides the only data available on half-life of elimination and AUC under steady-state conditions and on intrasubject variability. Although there are considerable differences in the pharmacokinetics among the four gestagens (LNG, norethisterone, desogestrel, and gestodene) used in oral contraceptives,[2] the remarks about LNG are also applicable to the other three gestagens.

The month-to-month variability in half-life of elimination and AUC may be considerable (up to 250%) in the same subject, even though the estimates were made in 3 consecutive months with the subjects under fairly "basal" conditions. This variability limits the extent to which estimates of pharmacokinetic parameters, determined even under steady-state conditions at one point in time, can be extrapolated to other times. This is particularly important for drugs such as oral contraceptives that are used on a long-term basis, because over the period of use, changes in the subject's physiology and social habits may accentuate the "basal" monthly variations. Although only half-life of elimination and AUC were analyzed in this report, similar variability most likely occurs in other pharmacokinetic parameters, but the available data are too meager for any of the gestagens to perform a proper analysis. The intrasubject variability described here was, as expected, always less than the intersubject variability. Another important aspect of intrasubject variability is the absence of any correlation between the rate at which a particular subject metabolizes the gestagen and estrogen components of an oral contraceptive.[7]

Although it has been suspected that the pharmacokinetics of any gestagen may depend on the particular formulation administered, evidence to substantiate this has so far been very tentative because the intersubject variation is large in relation to the differences in pharmacokinetic behavior between the formulations. The results presented here show marked differences in half-life of elimination and AUC, and therefore presumably in the other parameters, between two formulations containing the same dose of LNG administered with or

without estrogen when these are compared in the same subjects. Since the dose of LNG in the two formulations is identical, since LNG is completely absorbed, and since it is unlikely that there is any difference in the rate of absorption, the marked difference between the two formulations in bioavailability as assessed by AUC, with that for LNG + EE being about four times that of LNG alone, may be artifactual. This may indicate that for oral contraceptives, measurement of AUC is not a valid indication of bioavailability unless this term is rigorously defined.

From the evidence available, it is not possible to decide firmly which of the two basic processes (volume of distribution or clearance) that determine half-life of elimination is responsible for the differences in half-life of elimination between the two formulations. Although serum SHBG concentrations show a small decrease with LNG + EE, the decrease is greater with LNG alone, and consequently there will be a greater decrease in the binding of LNG. This decrease in binding will increase volume of distribution, which will tend to lengthen half-life of elimination, and volume of distribution (LNG) should be greater than volume of distribution (LNG + EE), but the increase is unlikely to be more than twofold. Since the dose of LNG is the same in both formulations and AUC (LNG + EE) is about fourfold AUC (LNG), the apparent clearance for LNG will be about fourfold that of LNG + EE, and this will decrease half-life of elimination. Thus the twofold difference in half-life of elimination between LNG + EE and LNG appears to be due to a twofold lengthening of half-life of elimination resulting from an increase in volume of distribution in group LNG and a fourfold shortening of half-life of elimination in group LNG resulting from the fourfold increase in clearance.

The extent to which the intrasubject variation in pharmacokinetics affects the pharmacodynamic response is not known. It seems, however, that both the intra- and intersubject variability in pharmacokinetics is much greater than the pharmacodynamic responses, and if this is so, the question is raised of whether there is any correlation between the pharmacokinetics of the gestagens and their pharmacodynamic effects. At present any correlation is obscure.

This possible lack of correlation with biologic response, the wide inter- and intrasubject variability in pharmacokinetic parameters, the problems that arise in their derivation and interpretation, and the biologic significance of most of these parameters appear to limit severely the usefulness of pharmacokinetic studies of the gestagens.

Protein binding of active ingredients and comparison of serum ethinyl estradiol sex hormone–binding globulin, corticosteroid-binding globulin, and cortisol levels in women using a combination of gestodene/ethinyl estradiol (Femovan) or a combination of desogestrel/ethinyl estradiol (Marvelon) and single-dose ethinyl estradiol bioequivalence from both oral contraceptives

Berlin, West Germany

Results from two clinical pharmacokinetic studies are given. The first study was an observational study in oral contraceptive users who took either a combination of gestodene and ethinyl estradiol (pill A, Femovan) or desogestrel and ethinyl estradiol (pill B, Marvelon). A total of 69 women (39 receiving pill A and 30 receiving pill B) were evaluated to determine serum ethinyl estradiol, sex hormone–binding globulin, corticosteroid-binding globulin, and cortisol levels. Samples were obtained on 1 day during the tenth to twenty-first days of pill intake. All women received the respective oral contraceptive for at least 3 months. The test power was such that an 80% difference of 1 standard deviation of each target variable would have been detected ($\alpha = 0.05$; $\beta = 0.1$). No statistically significant differences were found in sex hormone–binding globulin, corticosteroid-binding globulin, or cortisol serum levels between both groups. Time and height of maximum ethinyl estradiol levels were identical as was the area under the curves. Ex vivo protein-binding analysis of the progestins revealed a free portion of 0.6% for gestodene and 2.5% for 3-ketodesogestrel as the active metabolite of desogestrel. Sex hormone–binding globulin–bound portions were much higher for gestodene (75.3% ± 9.1%) than for 3-ketodesogestrel (31.6% ± 12%). The remaining fractions were bound to albumin. In a second study, ethinyl estradiol-bioequivalence from pills A and B was investigated in 18 women in a controlled, single-dose, randomized, crossover design. The area under the ethinyl estradiol serum levels were identical up to 4 hours after pill intake between both treatments. According to the relatively low variation in data in this group of women, a 10% difference in ethinyl estradiol-availability could have been detected. Both studies indicate that the pharmacokinetics of ethinyl estradiol were independent of the concomitantly administered progestin, that is, desogestel and gestodene. (Am J Obstet Gynecol 1990;163:329-33.)

Key words: Gestodene, desogestrel, ethinyl estradiol, bioequivalence, sex hormone–binding globulin binding

Recently time-dependent changes in the serum levels of progestin have been reported in women who use either a combination oral contraceptive containing 75 μg of gestodene plus 30 μg of ethinyl estradiol (EE_2) (Femovan, pill A) or 150 μg of desogestel plus 30 μg of EE_2 (Marvelon, pill B). It was found that relative to 3-ketodesogestrel, higher total serum levels of gestodene were reached after repeated administration.[1-3] Results revealed a clear dependency of gestodene levels on concomitant changes in sex hormone–binding globulin (SHBG) serum levels. As an additional explanation, it was suggested that an "impeded metabolism" of gestodene could have contributed to the increase in serum levels. A similar interpretation has been offered for higher increases in serum EE_2, corticosteroid-binding globulin, and cortisol levels found after intake of pill A compared with those of pill B in the same comparative study.[4]

The pharmacokinetics of sex steroids have been investigated extensively in the past.[5] Although various progestins show manifold differences in some important pharmacokinetic parameters, such as formation of active metabolite(s),[6] absolute bioavailability, terminal half-life of disposition from plasma,[7] and binding to carrier proteins,[8] their use in oral contraceptives was always defined by clinical experience and key studies on endocrinology. Furthermore, the daily pill intake schedule has never been adopted to pharmacokinetics.

The estrogen in most oral contraceptives, EE_2, is known for its large intersubject variability in pharmacokinetics.[9] Even oral bioavailability seems to vary to the same extent between subjects as within the same individual.[10] Therefore large groups of users are necessary to obtain a valid clinical response for small changes in EE_2 dose. In the past the EE_2 dose in combination oral contraceptives has been continuously lowered from 80 μg/day to 30 or even 20 μg/day to find an optimal balance between estrogen-dependent biochemical changes, efficacy, and bleeding control. Therefore the indication of increased serum EE_2 levels in pill A users[4] was assumed as the working hypothesis for two pharmacokinetic-clinical studies.

The aim of the first study was to investigate further the protein-binding characteristics of active ingredients, the serum levels of EE_2 and EE_2-dependent parameters, such as SHBG, corticosteroid-binding globulin, and cortisol, in two groups of women taking either pill A or pill B.

The aim of the second study was to check the EE_2 bioequivalence of both pills. The study has been performed in a controlled, single-dose, randomized, crossover design with a washout period of 1 week.

Material and methods

Subjects and trial designs. The details of subjects and studies are given in Table I.

Study 1 (group comparison) was an observational study in healthy women who used pill A or B for at least 3 months. The study was carried out at 5 locations (gynecologists) in Berlin and West Germany. After the purpose of the study was explained, the women were asked to donate blood immediately before and at specified times (Table I) after morning pill intake.

Study 2 was an open, single-dose, controlled, randomized crossover trial in 18 healthy women (Table I). The study protocol had been approved by an institutional review board and written informed consent was obtained. Between both treatments there was a washout period of 1 week.

Analysis. In study 1 all measurements were done in duplicate. Serum levels of EE_2 and gestodene were measured as previously described.[11, 12] SHBG, corticosteroid-binding globulin, and cortisol levels were determined by commercial kits (Diagnostic Products, Los Angeles, Calif., IRE Medgenix, Belgium, and H. Biermann GmbH, Federal Republic of Germany). Protein-binding experiments were carried out according to Hammond et al.[8]

EE_2 levels were analyzed in individual samples and serum pools representing time-averaged concentrations for the first 4 hours after pill intake. SHBG,

MIN/MAX, Minimum/maximum.

corticosteroid-binding globulin, and cortisol levels were also determined in these pools.

Analysis of samples from study 2 is ongoing. As the first results, serum levels of EE_2 in pooled samples are available in triplicate measures.

Statistical analysis. In study 1 groups were compared by an analysis of covariance with "day of cycle" and "duration of intake in months" as covariates. The null hypothesis was formulated as follows: mean values of all parameters are equal for both treatment groups.

The alternative hypothesis is that with given group size and a type 1 error of $\alpha = 0.05$ and a test power of $1 - \beta = 0.9$ a difference of $0.8\ \sigma = 80\%$ of 1 standard deviation) would be detectable with a t test.

The second study was evaluated by the Student t test for area under the curve (AUC)-EE_2 0 to 4 hours as a parameter for bioequivalence.

Results

Study 1. Protein binding of 3-ketodesogestrel and gestodene was analyzed in 28 and 37 serum pools, respectively. The results are given in Table II.

No specific binding was found for EE_2, and free fractions were identical under both treatments (1.7% ± 0.6% and 1.5% ± 0.2%).

Whereas 3-ketodesogestrel levels are not yet available, gestodene levels were characterized by AUC (0 to 4 hours) = 29.6 ± 10.4 ng · hr · ml^{-1} (n = 38).

Mean time courses of EE_2 levels in serum were similar in both treatment groups. Average pretreatment (0 hours) and 24 hours posttreatment levels between 26 and 28 pg/ml were nearly the same. Maximum EE_2 concentrations of 106 ± 38 pg/ml (gestodene group) and 129 ± 51 pg/ml (desogestrel group) were reached 1.8 and 1.6 hours after ingestion. No differences in AUC values – total (0 to 24 hours) and partial areas (AUC 0 to 4 hours) were found between both preparations (Table III).

Table IV. Serum levels of SHBG, corticosteroid-binding globulin, and cortisol in two groups of women using a low-dose combination (OC) containing either gestodene or desogestrel as the progestin

	Femovan	*Marvelon*
SHBG	n* = 38	n* = 27
nmol/L	186 ± 57	226 ± 64
MIN/MAX	92/299	94/363
CBG	n = 38	n = 38
μg/ml	89 ± 14	93 ± 14
MIN/MAX	57/121	64/122
Cortisol	n = 37	n = 27
ng/ml	281 ± 80	280 ± 62
MIN/MAX	145/461	173/387

CBG, Corticosteroid-binding globulin.

*Missing figures from two to three women in any parameter compared with Table III are because of the low sample volume left after EE_2 analysis.

AUC values (0 to 4 hours) as determined by single sample or pooled sample analysis were in complete agreement, demonstrating no necessity for pretreatment value subtraction. In every case pooled sample concentrations were clearly within the sensitive part of the standard curve of the assay. Under both preparations a wide range of SHBG levels was obtained (Table IV).

On average, 226 ± 64 nmol/L of SHBG was found for the desogestrel group and 186 ± 57 nmol/L for the gestodene group; the difference was not significant. Corticosteroid-binding globulin levels were almost identical numerically. Again, no statistically significant difference was found for cortisol serum levels measured under both preparations (Table IV).

Study 2. EE_2 levels in pooled serum samples were identical after ingestion of both OCs (Fig. 1). AUC (0 to 4 hours) after Femovan intake was 348 ± 65 pg · hr · ml^{-1} (range, 224 to 471) and 343 ±

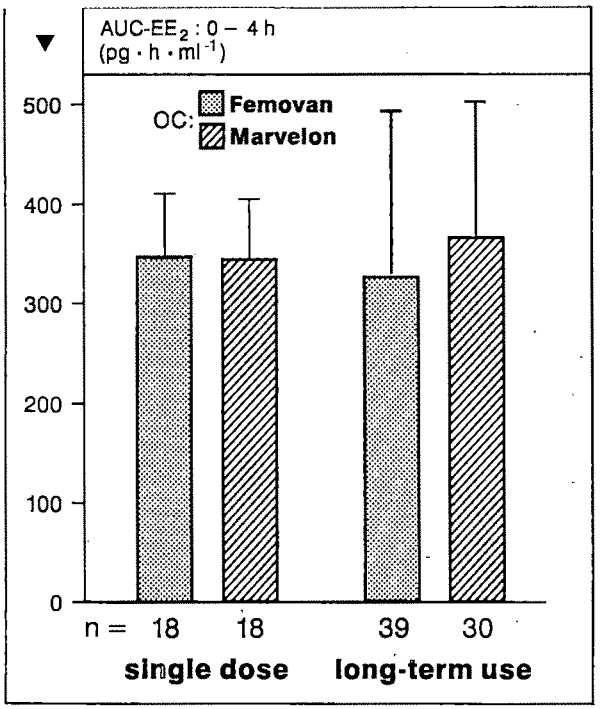

Fig. 1. Comparison of systemic availability of EE_2 between two low-dose combination OCs. The single-dose controlled, randomized, crossover study was conducted in 18 women, whereas the long-term study was conducted in two groups of 30 and 39 users, respectively. Means ± standard deviation of the area under the EE_2 curve up to 4 hours after pill intake are compared.

69 pg · hr · ml^{-1} (range, 222 to 462) after Marvelon treatment. Intrasubject variance of this parameter accounted for only about half of intersubject variance. According to the relatively low data variation, a 10% difference in EE_2 availability could have been detected.

Comment

Recently a new type of pharmacokinetic study has been published that compared actual progestin levels after repeated intake of two low-dose OCs containing different progestins (desogestrel and gestodene, respectively) at different dosages.[1-3] Active ingredients differ from each other by physicochemical properties (*n*-octanol/water partition coefficient is 285 for gestodene and 933 for 3-ketodesogestrel), absolute bioavailability, and metabolic clearance rate. Therefore, dose-corrected serum levels of equal height would not be expected. One very important property governing total serum progestin levels is protein binding, specifically, the extent to which a given progestin is bound to SHBG. In addition, the concentration of SHBG will markedly influence actual levels. The observation that steady-state levels of gestodene (daily dose, 75 μg) were four to five times higher than 3-ketodesogestrel levels (daily desogestrel dose, 150 μg) could be explained by the EE_2-dependent increase in SHBG during pill intake.[1,2] The present results confirm this explanation, showing that gestodene was highly (about 75%) bound to SHBG, whereas about 32% binding was found for 3-ketodesogestrel. Consequently, the free portion in serum was much lower for gestodene (0.6%) than for 3-ketodesogestrel (2.5%). According to the different protein-binding characteristics of gestodene and 3-ketodesogestrel, the free concentrations of both progestins are almost identical, although total serum levels differed about fourfold to fivefold.

The reason for higher increases in serum levels of gestodene compared with levels of 3-ketodesogestrel is the 10 times higher affinity to SHBG, which is reflected by the much higher proportion of specifically bound gestodene. Compared with 3-ketodesogestrel, gestodene is distributed differently in the body.

There is no need for additional (more speculative) explanations, such as "impeded metabolism," to interpret differences in actual progestin serum levels.

The present studies failed to confirm the observation of increased EE_2 serum levels with pill A compared with pill B.[4] Both trials were designed to detect statistically significant differences lower than those found previously, even at the first day of treatment.[4] This was the reason for our study 2, because in the single-dose bioequivalence study, an intraindividual comparison of EE_2 bioavailability could be accomplished. Interestingly, the data did not vary to the same extent as in study 1, and therefore an even 10% difference of mean EE_2-AUC values could have been detected between both preparations.

Therefore in conclusion the pharmacokinetics of EE_2 are independent of the coadministered progestins gestodene and desogestrel. Consequently, study 1 failed to show differences in the EE_2-dependent increase in corticosteroid-binding globulin and corticosteroid-binding globulin-dependent cortisol serum levels.

ORAL CONTRACEPTIVES AND CARBOHYDRATE METABOLISM

Clinical aspects of the relationship between oral contraceptives, abnormalities in carbohydrate metabolism, and the development of cardiovascular disease

Ulysse J. Gaspard, MD, PhD,[a] and Pierre J. Lefebvre, MD, PhD[b]
Liège, Belgium

Although large epidemiologic studies indicated no difference in the frequency of diabetes mellitus in nonusers and everusers of high-dose combination oral contraceptives, other studies had shown an increased risk of impaired glucose tolerance in current users, which is estimated to be roughly twice as frequent as that in nonusers. Women at risk of developing impaired glucose tolerance while receiving high-dose oral contraceptives either had previous gestational diabetes mellitus or were older, obese, or had a positive family history of diabetes mellitus. The tendency to decreased glucose tolerance seems essentially related to the dosage and chemical structure of the progestogen used in oral contraceptives, namely, estrane and particularly gonane progestins. However, increased frequency of impaired glucose tolerance and potentially diabetes mellitus are obviously not linked to the use of the more potent gonane progestins. The use of low-dose oral contraceptives, particularly with reduced progestogen content (such as in the triphasic formulations and last-generation monophasic preparations), is accompanied by a low risk of impaired glucose tolerance, even in previous gestational diabetes mellitus. The mechanism of decreased glucose tolerance in oral contraceptive users is unknown but seems related partially to increased peripheral resistance that is potentially caused by a postreceptor defect in insulin action. Changes in insulin production or metabolic clearance rate are not excluded by recent, sophisticated investigations of carbohydrate metabolism in oral contraceptive users. Impaired glucose tolerance and diabetes mellitus, chronic hyperglycemia, and hyperinsulinemia are believed to increase atherogenic risk either by their direct action or their effects on lipid metabolism. Newer epidemiologic studies now indicate that the incidence of cardiovascular disease in low-dose, low-risk, current oral contraceptive users has been substantially decreased. The use of low-dose oral contraceptives with reduced dosages of better adapted progestogens seems effective in decreasing alterations in carbohydrate metabolism and may thereby contribute to decrease further atherogenic risk in oral contraceptive users. (Am J Obstet Gynecol 1990;163:334-43.)

Key words: Glucose tolerance, insulin resistance, cardiovascular risk, oral contraception

Excess mortality and morbidity from cardiovascular disease (CVD) was observed in the 1970s mainly in women over 40 years of age, who had other established risk factors of CVD and who used combination oral contraceptives (OCs) containing high dosages of both estrogens and progestogens.[1] These events were related tentatively to increased atherogenicity and thrombogenic activity of OCs resulting from their steroid content. Accordingly, attempts directed at reducing the estrogen content of OCs were successful in decreasing thromboembolism,[2] and a further reduction of the progestogen content helped decrease vascular disease, mainly on the arterial side.[3] Moreover, Realini and Goldzieher,[4] in a reanalysis of these epidemiologic data, concluded that OC use may amplify well-known risk factors of CVD (such as cigarette smoking, hyperlipoproteinemia, hypertension, and diabetes) rather than be an independent risk factor alone.

Newer epidemiologic studies now indicate that current use of combined OCs with low dosages of both estrogen and progestogen by selected women at low risk for CVD is accompanied by a definitely low incidence of cardiovascular accidents. The latter now seems related more to coagulation disturbances than to enhanced atherogenesis.[5-7]

Table I. Glucose tolerance in high-dose OC users

Type of studies	*No. of patients*	*Duration (mo)*	*No. of diabetics*
Oral and IV glucose tolerance tests in normal women receiving high-dose OCs	867 (22 studies)	1-48	34 (3.9%) (in 15/22 studies, no incidence of diabetes)
Glucocorticoid glucose tolerance in normal women receiving high-dose OCs	122 (4 studies)	1-17	61 (50%)
High-dose OCs in women with previous GDM	32 (4 studies)	0.5-6	14 (44%)

Data compiled from Kalkhoff RK. J Steroid Biochem 1975;6:949-56.
IV, Intravenous.

A reduction of the atherogenic risk by lowering the estrogen and more specifically the progestogen content of pills is probably partially achieved by reducing their adverse actions on lipoprotein and carbohydrate metabolism.[8]

Because diabetes mellitus (DM) is considered a primary risk factor for CVD[9] and because it has been known for more than 26 years[10] that OC use increases the risk of developing altered glucose tolerance, the purpose of this review is to outline some of the main data related to changing OC composition and its impact on carbohydrate metabolism in relation to the risk of CVD.

Effects of high-dose OCs (Table I)

In a large population of women taking high-dose OCs (50 to 150 μg of ethinyl estradiol [EE] and a high amount of progestogen), the 1-hour glucose tolerance-test (GTT) yielded serum glucose levels >11 mg/dl than those in non- or postusers, and the effect of the OC was added to the effects of age, obesity, and family history of diabetes. These changes were reversible on discontinuation of OCs.[11] Kalkhoff et al.[12] reported that irrespective of the length of OC intake, a relative incidence of impairment of glucose tolerance that approximated 20% developed in normal women using high-dose OCs.

A review of 22 studies of 867 women with normal glucose tolerance as assessed by an oral or intravenous GTT showed conversion to a diabetic-type test in 34 patients (3.9%) after 1 to 48 months of high-dose OC use. It is noteworthy that this increased frequency of abnormal glucose tolerance was observed in only 7 of the 22 studies. The existence of diabetogenic stress in users of high-dose OCs was further substantiated by investigations of glucocorticoid-sensitized GTTs, which yielded 50% abnormal responses, which corresponded to a 10- to 20-fold increase in the frequency expected in a general population.[12] These diabetic responses after prednisolone use were associated with subnormal plasma insulin responses during the first hour of the test as usually seen in patients with subclinical diabetes. However, return to a normal glucocorticoid-sensitized GTT was observed after 1 to 2 months of discontinuation of OC use.

Two other recent studies are worth reporting: in the Second National Health and Nutrition Examination Survey, impaired glucose tolerance (IGT) was observed in 13% of current high-dose OC users.[14] The second study reported 2-hour oral glucose tolerance test (OGTT) results from the Walnut Creek Contraceptive Drug Study, a 10-year prospective follow-up study. The 16% prevalence of IGT (including 2% of DM) was substantially higher than that of 8% in nonusers (including 1% of DM).[15]

In four studies reviewed by Kalkhoff[13] and totaling 32 women with previous gestational diabetes mellitus (GDM), a 2-week to 6-month duration of high-dose OC use was associated with a mean change of 44% in DM, a situation that is not always reversible on discontinuation of OCs. Moreover, in non-insulin-dependent DM, a deterioration in glucose tolerance was induced by high-dose OCs in 7 of 10 women, and in those suffering from insulin-dependent DM, the results were more variable, from minor changes in insulin requirements to extreme lability of insulin control.[13] In most of these cases, the response to OGTT or intravenous GTT was comparable as a whole: with high-dose OCs, a slight basal increase in fasting blood glucose and plasma insulin was observed, and after glucose loading, a lowered tolerance to glucose developed, eventually attained a pathologic level, and was associated with increased insulin response throughout the test or more markedly after 1 hour. Therefore the pill was considered to decrease insulin sensitivity and to represent a diabetogenic stress that preferably should not be administered to women with preexisting abnormalities in carbohydrate metabolism.

However, two important epidemiologic studies seemed more reassuring about the so-called diabetogenic effect of OCs. First, the survey of the Royal College of General Practitioners Study, which was in agreement with the Oxford FPA Study,[16] showed no difference in the frequency of DM incidence between high-dose OC current users (67,990 women-years), past users (42,663 women-years), and nonusers (111,252 women-years). They firmly concluded that "while it is still desirable to monitor OC users whose medical and family history indicate an increased likelihood of developing diabetes, the present results do not support

the belief that this contraceptive method increases the risk of DM."

Second, Duffy and Ray[17] reported a mean 8½-year follow-up study of 8652 women, which was made up of users, exusers, and nonusers of high-dose OCs. Screening for abnormalities in glucose metabolism revealed 118 cases of IGT or DM, with the same prevalence in carbohydrate abnormalities in all three categories of women. In particular, no permanent change in glucose status was observed as a result of OC use, and increased glucose intolerance was observed in women who were older, had a positive history of diabetes, or had a greater relative weight.

A preliminary conclusion from these sometimes divergent observations is that use of high-dose OCs is capable, probably in a predisposed population, of chronically increasing blood glucose and insulin levels and the incidence of IGT in the population, probably in a reversible manner. However, these long-term metabolic changes are of concern because they may facilitate atherosclerosis.[18]

Responsibility of the different steroid components of OCs in alterations in carbohydrate metabolism in users and impact on atherogenesis

As they relate to the estrogen compounds, ethinyl estradiol and mestranol, the studies of Spellacy et al.[19] showed that long-time use of these compounds did not significantly affect either blood glucose or plasma insulin after an OGTT. However, after 2 years of treatment with 80 μg of mestranol, the same group reported a small increase in serum glucose and insulin levels during an OGTT. In case of IGT, no further deterioration in glucose tolerance was observed with estrogen treatment.[20]

In contrast, numerous data, most of which were extensively reviewed by Spellacy[21] and Wynn,[22] indicate that progesterone, 17-acetoxyprogesterone derivatives, and 19-nortestosterone–derived progestins can, in an increasing order, increase both glucose and insulin levels after oral or intravenous administration of glucose, even if these drugs are given alone and in small dosages.

That not only the dose but the type of progestogen may be important is shown in several publications of Spellacy et al.,[21, 23] suggesting that megestrol acetate, a 17-acetoxyprogesterone derivative, would not affect glucose or insulin levels at a dose of 0.5 mg/day for 1 year, whereas 19-nortestosterone estrane derivatives, such as norethindrone or ethynodiol diacetate, would moderately and the gonane derivative norgestrel would markedly increase both blood glucose and plasma insulin levels.[21]

It is noteworthy that in the Walnut Creek Contraceptive Drug Study,[15] an analysis of glucose tolerance data by multiple linear regression analysis was undertaken to define dose-response relationships between the OCs and fasting, 1- and 2-hour glucose values: synthetic estrogens were not found to be related to measures of glucose tolerance, whereas examination of the regression coefficients indicated a 5 to 10 mg/dl increase in serum glucose for both 1- and 2-hour test results per milligram of structurally similar estrane progestins (norethindrone, norethindrone acetate, and ethynodiol diacetate). For the gonane progestin norgestrel, the slopes reflected an 18 of 35 to mg/dl increase/mg. One would expect that norgestrel-containing OCs would show the greatest decrease in glucose tolerance. However, because this compound or its active enantiomer levonorgestrel powerfully inhibits gonadotropins, it can be used in OCs in relatively lower amounts than estrane progestins, so that its impact on carbohydrate metabolism is finally brought to a comparable level.

In this respect, the prevalence of IGT and DM according to progestin exposure subgroups in the study of Perlman et al.[15] shows low values for the group taking a norgestrel-containing OC and is in fact slightly lower than that for other groups taking OCs containing estrane progestins.

Thus it must be remembered that not only nature and potency but also dose and type of administration must be considered, as well as adequately designed prospective studies conducted, for each estrogen-progestin formulation before any appreciation of its effect on glucose metabolism can be given accurately. If most of the impact on carbohydrate metabolism in OC users is related to the dose and potency of the progestin content, adaptation of low-dose OC formulation is mandatory in view of reducing carbohydrate alterations to a minimum, because chronic abnormalities can lead to increased cardiovascular morbidity and mortality. It is well known that DM is an independent risk factor of macrovascular disease, inducing a twofold to threefold increase in cerebral and coronary atherosclerosis and a sixfold to 20-fold increase in the arteriopathy of the lower limbs, with a substantial overall risk in young patients[24] and a particularly high incidence in women.[25]

IGT, as reflected by an increase in 2-hour blood glucose values, can be related to a twofold increase in cardiovascular death.[26, 27] Hyperinsulinemia, either in the fasting state or at 1 or 2 hours of an OGTT, has a role as a risk factor of CVD independent of other classic risk factors and at any level of blood glucose, with a twofold increase in the coronary disease mortality rate.[28-30] Chronic hyperinsulinemia may induce stimulation of vascular smooth muscle cell proliferation[31] and may cause alterations in lipoprotein metabolism by not only inducing the synthesis of very low–density lipoprotein triglycerides but also by decreasing high-density lipoprotein cholesterol and particularly the

HDL_2 cholesterol subfraction (the so-called cardioprotective fraction), as shown in noninsulin-dependent DM.[32, 33] Although still somewhat controversial,[34] these observations may be relevant to the increased risk of atherogenesis in cases of hyperinsulinemia.

Certainly in that regard, the new OCs with overall reduced levels of estrogen and progestin, with particular emphasis on reducing the most potent progestins such as levonorgestrel and other gonanes, should be suited better to exerting only a minor impact on carbohydrate metabolism and thereby partly on potential atherogenicity. Moreover, because abnormalities in glucose metabolism may be observed in OC users, particularly, if additional risk factors such as obesity, family history of diabetes, age, or antecedent of GDM are present, it is essential to evaluate how to minimize the risk in OC users by proper patient selection.[21]

Effects of low-dose OCs (Table II)

As the first "sub fifty" pills containing lower levels of EE combined with low doses of progestins were introduced in the mid-1970s and became widely used only in the 1980s, epidemiologic data with a sufficiently long follow-up period are very scarce.

A large prospective study on diabetic risks was initiated in 1985 in the greater Paris area (Telecom Study) by Eschwege et al.[35] with 1112 healthy women of reproductive age participating. They were analyzed on a cross-sectional basis according to their use of oral contraception: 369 women (30%) were current OC users, and among them 79% used low-dose pills. After adjustment for age, weight, and risk factors for diabetes, those taking the pill had significantly higher fasting serum insulin, triglycerides, and 2-hour 75 gm OGTT blood glucose levels compared with those who did not.

In this restricted series no difference was seen between users of high- and low-dose OCs.

These authors concluded that the insulin-resistance markers, which have recently been cited as risk factors of ischemic vascular disease, should still be carefully monitored in pill users.

Most of the studies on which we rely for analysis of carbohydrate metabolism during use of low-dose OCs have restricted numbers of women, usually 10 to 20, highly selected for exclusion of vascular risk factors, and usually subjected for 6 to 12 months (rarely more) to OGTTs in order to monitor mainly changes in blood glucose and plasma insulin and eventually circulating levels of pyruvate, glucagon, C-peptide, and glycosylated hemoglobin A_1C, as well as monocyte or erythrocyte insulin receptors. Thus we must rely more on biochemical than epidemiologic data to appreciate the potential of these drugs to alter glucose metabolism. On the contrary, well-designed biologic studies can also shed new insight into the mechanism of action of contraceptive steroids on carbohydrate metabolism and potentially unrecognized metabolic alterations.

Low-dose OCs containing levonorgestrel

The effects on carbohydrate metabolism of the combination preparations containing an intermediate dose of levonorgestrel, 150 μg/day, are controversial. Ahren et al.[36] did not observe any increase in blood glucose, and plasma insulin levels when EE 30 μg + levonorgestrel 150 μg was used for 12 months either in an oral formulation or as a vaginal ring.

Vandervange et al.[37] subjected 10 healthy women to the same combination OC and did not observe statistically significant changes in plasma glucose and insulin levels and areas under the curves when OGTTs were compared before and at 6 months.

The World Health Organization multicenter trial[38] compared two low-dose combination OCs—EE, 35 μg, with norethindrone, 1 mg, and EE, 30 μg, with levonorgestrel, 150 μg, for 12 months in 847 users. In both pill groups, an increase in 2-hour glucose was observed at both 3 and 12 months without any significant difference between groups. Eight percent of OC users had IGT compared with 4% in an intrauterine device control group (n = 195). However, at 12 months, one third of OC users with IGT detected after 3 months had returned to normal glucose tolerance.

Wynn[39] observed a deterioration in glucose tolerance that increased with time for up to 36 months of study when the same OC containing EE 35 μg + levonorgestrel 150 μg was used. An accompanying increase in insulin response developed during OC use, but this increase could not prevent an increase in the ratio of incremental glucose area: incremental insulin area. IGT developed in six women, three of whom had overt DM after 3, 12, and 30 months, respectively. However, the major drawback of this study is an uncommonly high drop-out rate: 210 women entered the study and only 17 remained in the study after 3 years, which, of course, does not allow for epidemiologic conclusions to be drawn. It is noteworthy that in a small group of 10 women with previous GDM using the same EE 35 μg + levonorgestrel, 150 μg preparation for 6 months, IGT was not observed, but a significant rise in plasma insulin values was seen.[40] Because of these controversial results, it was interesting to analyze the results obtained when the influence of the triphasic formulation containing EE and levonorgestrel was studied, since this preparation contained only a mean daily dose of 92 μg of levonorgestrel, a substantial decrease of 39% compared with the monophasic "low-dose" preparation. In one preliminary study, blood glucose and plasma insulin levels increased after 6 months, but these changes were not considered clinically relevant.[41]

In a careful 12-month prospective study,[42] we compared 24 treated subjects at 0, 6, and 12 months of use with a group of matched nonusers. No change in glucose tolerance was recorded in any individual during treatment, and a moderate but statistically significant increase in plasma insulin response was only transiently observed during the sixth month of study. In addition, no changes in the number of and affinity of insulin erythrocyte receptors were recorded. These results were at odds with a previous 6-month study,[43] in which we observed a slight decrease in glucose tolerance that was associated with a decrease in insulin response when compared with pretreatment levels. However, this difference may also be related to circannual changes in glucose-insulin homeostasis as previously observed by Reinberg et al.[44] The protocol of our subsequent study was modified accordingly to avoid this physiologic interference. In a study of 10 women receiving this triphasic combination for 6 months, Vandervange et al.[37] were unable to observe any alteration in carbohydrate metabolism except for a slight but significant increase in blood glucose at 30 minutes of the OGTT at 6 months of use. Very recently Spellacy et al.[45] reported that OGTTs performed on 28 women before and after 12 months of using this levonorgestrel triphasic OC showed no significant changes in glucose or insulin. Moreover, a study conducted with this levonorgestrel triphasic OC for 6 months in normal women and those with previous GDM did not show significant changes in blood glucose, or plasma insulin, and glucagon response to oral glucose at 2 and 6 months despite higher blood glucose levels before entering the study in women with previous GDM.[46]

These same authors analyzed under the same clinical circumstances the variation in insulin sensitivity in women during a 6-month period of levonorgestrel

triphasic OC treatment using the hyperinsulinemic-euglycemic clamp technique.[47] They observed that use of this OC decreased slightly, but not significantly, insulin sensitivity in healthy women. In previous GDM the decrease was slightly more pronounced and reached significance, but this decrease was not sufficient to alter glucose tolerance.[47] From these numerous studies devoted to OCs containing either intermediate (150 μg) or low (92 μg, mean daily dose) dosages of levonorgestrel and considering the number of women studied, including high-risk groups (GDM), the length of the studies, and the accuracy of the methodologies (use of control groups, sophisticated investigation such as the clamp technique), it seems that a drastic reduction in the dose of this potent gonane progestin is associated with a substantial reduction or even a lack of adverse effects on carbohydrate metabolism. A minor influence on IGT that developed in nondiabetic women cannot be discarded—as for other low-dose OCs such as EE, 35 μg, and norethindrone, 1000 μg—during use of EE, 35 μg, and levonorgestrel, 150 μg, formulations.

Low-dose OCs containing desogestrel

Although preliminary data[48] indicate that after 6 months of use with monophasic EE, 30 μg, with desogestrel, 150 μg, significant increases in blood glucose and insulin levels were recorded, our study[43] did not reveal any change in glucose tolerance but detected a slight decrease in insulin response during the OGTT performed at 6 months of OC use. At that time it was felt that circannual changes could partly account for this observation. However, in a recent prospective study of 21 women taking this monophasic OC for 12 months, we observed a slight borderline increase in blood glucose levels (without any trend to IGT) and again a decrease in insulin response compared with pretreatment and 6-month responses, whereas C-peptide was significantly increased. This could be related to a somewhat increased rate of metabolic clearance of insulin with use of this drug, but this necessitates more detailed studies (Jandrain B, Humblet D, Jaminet C, Scheen AJ, Gaspard U, Lefebvre PJ. Unpublished data). In the study by Vandervange et al.[37] no change in glucose and insulin response and hemoglobin A_{1c} and glycosylated proteins could be observed after 6 months of use with this monophasic OC. Moreover, using the recently introduced monophasic formulation EE, 20 μg, and desogestrel, 150 μg, no alteration in fasting insulin and glucose levels was seen after 6 months of use with this OC, and the response to OGTT was also unchanged.[49]

Low-dose OCs containing gestodene

This gonane progestin recently introduced in monophasic OCs (EE, 30 μg, and gestodene, 75 μg) or in a triphasic formulation (EE, 32 μg, and gestodene, 79 μg, mean daily dosage) is interesting because of its potent gonadotropin-inhibiting effect, which allows it to be used in very low dosages in OCs.

Preliminary results of the study of Rabe et al.[50] performed on 28 women during 12 months using the monophasic formulation showed a slight increase in glucose and insulin levels during OGTTs, with no subject developing IGT. Our results with the gestodene triphasic formulation are particularly encouraging, because they show[42] in the 20 women using this OC for 12 months that glucose tolerance and insulin response during OGTTs are unchanged. This gestodene triphasic OC behaved even better than the levonorgestrel triphasic OC with which it was prospectively compared.

Low-dose OCs containing norethindrone

We reported the results of the World Health Organization Study on the monophasic formulation EE, 35 μg, and norethindrone, 1000 μg, which showed increased blood glucose levels at 3 and 12 months of use, and was associated with a slight increase in the incidence of women with IGT during treatment.[38] No change in carbohydrate metabolism was apparently observed with low-dose combination OCs containing either 500 or 400 μg of norethindrone.[51, 52] However, it must be remembered that 1 year of use of progestogen-only pills containing 350 μg of norethindrone or 250 μg of ethynodiol diacetate, another estrane progestin, enhanced blood glucose and plasma insulin concentrations despite the small dosage of these "less potent" (versus gonane progestins) steroid compounds.[53, 54] In the study of Rabe et al.,[55] the triphasic preparation containing EE, 35 μg + norethindrone, 750 μg, caused a transient increase in 1- and 2-hour blood glucose values and plasma insulin levels. At 12 months, however, the differences in glucose tolerance and insulin response were no longer statistically significant and no case of progression to IGT was recorded. The lack of effect on glucose tolerance with this OC was also recently reported by Spellacy et al.[45] in 33 women after 1 year of use.

Low-dose OCs containing cyproterone acetate

Cyproterone acetate is a pregnane progestin with antiandrogenic and antigonadotropic activities, usually used in high dosages for the treatment of hirsutism and other clinical conditions.[56] As discussed earlier, 17-acetoxyprogesterone–derived progestins have less metabolic impact than nortestosterone-derived progestins.[13] Indeed, an interesting study of Seed et al.[57] with sequential use of EE and cyproterone acetate at high dosages (10 to 20 times that used in OCs) showed decreased glucose tolerance and increased insulin levels in treated women. It did not, however, clearly ascertain whether increased insulin response was related to in-

creased pancreatic output, because C-peptide levels were not uniformly increased. In a recent still unpublished study (Jandrain B, Humblet D, Jaminet C, Scheen AJ, Gaspard U, Lefebvre PJ), we showed in 19 healthy women using a low-dose combination of EE, 35 μg, with cyproterone acetate, 2 μg, a slight decrease in glucose tolerance at 12 months of use and an associated modest increase in insulin and C-peptide responses during OGTTs, probably related to a slightly decreased insulin sensitivity. No case of progression to IGT was observed in this study. These results are well in agreement with the fact that pregnane compounds have only a limited impact on carbohydrate metabolism; a clearcut difference with the effects of low-dose combined OCs containing 19-nortestosterone–derived progestins is not observed despite low or even antiandrogenic properties of the former compounds. It should be remembered, however, that natural progesterone itself is not devoid of some effect on glucose metabolism.[22]

Comment

Recent epidemiologic studies[58] indicate that selection of women with low levels of recognized risk factors for CVD, such as smoking, hyperlipoproteinemia and hypertension, and the use of low-dose OCs (i.e., low estrogen doses combined with low progestogen dosages) are associated with a particularly low incidence of CVD. In fact low-dose OCs are considered amplifiers of risk factors and not primary risk factors by themselves.[4] Excess mortality or morbidity caused by CVD is restricted to current users of low-dose OCs only and are probably related to persistent excess of thrombogenic rather than atherogenic activity of these low-dose OCs.[58] The atherogenic risk of high-dose OCs is partly attributable to their adverse effects on lipid and carbohydrate metabolism.[59] As it relates to carbohydrate metabolism, it is now well established that DM, and very probably chronic hyperglycemia and hyperinsulinemia, can be considered risk factors of atherosclerosis.[18] Progestins contained in OCs, most of which are derived from 19-nortestosterone, have the potential to decrease glucose tolerance and increase insulin resistance by mechanisms still largely unknown. In some studies the use of standard dose OCs containing high levels of these progestins has been associated not only with biochemical alterations in the carbohydrate metabolism previously described but also with a trend to increasing the incidence of IGT and even progression to overt DM, which is sometimes not reversible, despite discontinuation of the OCs.[13]

However, large epidemiologic studies[16, 17] could not substantiate with long-term follow-up of large populations of women taking high-dose OCs any trend to increased incidence of DM or even IGT. In fact this incidence was increased in older women with obesity, a positive family history of DM, or previous GDM, and not specifically in relation to OC use. Notwithstanding this reassuring observation, it remains that high-dose OCs can chronically increase blood glucose and plasma insulin levels and may contribute to atherogenesis and excess CVD, as observed in earlier epidemiologic studies.[1] The progestin part of the OCs is mainly responsible for alteration in carbohydrate metabolism,[21] and among progestogens, 19-nortestosterone derivatives have more impact than 17-acetoxyprogesterone derivatives. Within 19-nor progestins, the more potent gonane derivatives, such as norgestrel, provoke more changes in carbohydrate metabolism than do estrane compounds.

However, the potential of norgestrel to increase the incidence of IGT and DM has not been demonstrated[15] inasmuch as the dose of this progestin can be safely reduced in OCs because of its potent antigonadotropic activity; this reduction is instrumental in decreasing the effect of norgestrel on carbohydrate metabolism.

A large number of studies, many of which are summarized in Table II, have been devoted to the impact of low-dose monophasic and triphasic OCs, all of which are characterized by low levels of estrane, gonane, or pregnane progestogens.

Most of these prospective studies have used repeated, standardized, oral glucose loads to assess before and at 3 to 12 months of use (rarely longer) the effect of low-dose OCs on carbohydrate metabolism. Most point to only slight decreases in glucose tolerance (usually mean areas under glucose curves + 10% to 15% compared with pretreatment values) with very rare cases of progression to IGT, if any. Usually a mild increase in insulin response to glucose is observed (mean areas under insulin curves + 10% to 30%) and is often interpreted as a reflection of increased insulin resistance, potentially at the postreceptor level.

Decreased insulin sensitivity is supported by analysis of the hyperinsulinemic-euglycemic glucose clamp technique[47] in users of low-dose levonorgestrel triphasic OCs. In a few studies, monocyte or erythrocyte insulin receptor number and affinity have been analyzed in relation to pill use, and the absence of change[42, 43] or slight changes[60] were observed, with no relation to changes in glucose tolerance. Glucagon basal levels or suppressibility during OGTTs was mainly unchanged or decreased in cases of OC intake in which insulin response to OGTT was not increased, such as during use of the monophasic low-dose EE + desogestrel, or enhanced in cases in which insulin response to OGTT was also increased, such as during use of the triphasic EE + levonorgestrel or the monophasic EE + cyproterone acetate.[42, 43] Despite some discrepancies in the results obtained, most of these metabolic studies

point to a low potential for low-dose pills to alter carbohydrate metabolism. Most changes observed are not even statistically significant, and when they are, the clinical relevance of these small differences can be questioned. Moreover, because of the low dosages of progestogens used in the new OCs, no study seems able to show a difference between pills containing <1 mg of norethindrone, <150 μg of levonorgestrel, or containing low dosages of desogestrel and gestodene, as far as carbohydrate metabolism is concerned.

However, many of these studies show a number of worrisome shortcomings that reduce considerably the interest and potential meaning of the results. First, and this is in agreement with the assertions of Crook et al.,[61] prospective studies of carbohydrate metabolism should be directed to clinically well-characterized homogeneous populations of women, with a sufficient number of subjects (probably 20 or more in relation to the methodology used) and for a sufficient duration of time (probably 12 months or more). The design of the studies should be more standardized, and circannual rhythms of glucose metabolism must be taken into account.[34]

The use of glucose challenge tests has been fruitful despite their well-known shortcomings. However, they should usually be better standardized, and the data related to blood glucose and plasma insulin levels generated in the studies should be more carefully analyzed and described.

This would at least help to more easily compare these studies. New large-scale epidemiologic studies, such the recent and incipient Telecom Study,[35] are needed to better ascertain whether low-dose pills are associated with a continuing low vascular risk.

Moreover, it is mandatory to understand better the mechanism underlying decreased tolerance to glucose in pill users by indepth studies of pancreatic B-cell function, insulin release, and kinetics during OC use. In particular, regular assessment of C-peptide levels should be part of these studies. The use of the euglycemic clamp technique at different insulin levels, analysis of tracer kinetics, and indirect calorimetry should help to better characterize insulin sensitivity. Alternatively, the use of the recently described minimal modeling method[62] could be very helpful to assess insulin sensitivity and B-cell function during OC use. In addition, studies of insulin receptor properties and postreceptor intracellular events should be envisaged.

Indepth study of the effects of different progestogens contained in OCs could well uncover different mechanisms of action more specific of a given steroid. For instance, such a progestogen might particularly alter postreceptor intracellular metabolism of glucose, whereas another progestin may more specifically alter the metabolic clearance rate of insulin. Uncovering such mechanisms may help develop progestins that potentially are more adapted to their contraceptive function, with a lesser impact on carbohydrate metabolism, because chronic hyperglycemia and hyperinsulinemia, even of a moderate nature, are best to be avoided as far as CVD is concerned.[18]

Mechanism of action of oral contraceptives on carbohydrate metabolism at the cellular level

Sven O. Skouby, MD,[a] Ole Andersen, MD,[b] Kresten R. Petersen, MD,[a] Lars Mølsted-Pedersen, MD,[a] and Claus Kühl, MD[a, b]

Copenhagen and Klampenborg, Denmark

Although the available scientific data on the undesired metabolic effects of sex steroids have accumulated rapidly, most are of a descriptive nature, and only a few studies elucidate the impact at the cellular level and the possible interrelationship between different metabolic systems. This review summarizes the influence of different contraceptive steroid combinations on glucose metabolism and points to the possible mechanisms behind a disturbance of the euglycemic homeostasis with a concomitant change in lipid metabolism. Today the general concept is that the influence of combined sex steroid products on glucose metabolism is mainly caused by the progestogen components, although artificial estrogens may act synergistically. The diabetogenic effects of the progestogens make it important to consider the development during the last decade of the new more selective progestogens of the gonane type. From recent studies it seems, however, that intake of contraceptive combinations of ethinyl estradiol in combination with these types of gonanes, such as desogestrel and gestodene, may also be accompanied by increased insulin resistance, specifically, a hyperinsulinemic response to a glucose challenge despite unchanged glucose values compared with a baseline test. This is similar to observations made with combinations of ethinyl estradiol and other more traditional types of progestogens of the gonane and estrane type. It is conceivable that the diabetogenic effects of the progestogens are caused by a change in insulin receptor binding or a postreceptor defect in the cellular insulin action. The clinical implications of the diabetogenic effects of the sex steroids are hard to interpret, but more long-term exposure of arterial tissue to elevated concentrations of glucose and insulin results in inhibition of lipolysis and synthesis of cholesterol and triglycerides, which result in the development of lipid-filled lesions—fatty streaks—similar to those of early atherosclerosis. (AM J OBSTET GYNECOL 1990;163:343-8.)

Key words: Oral contraceptives, glucose metabolism, insulin resistance, lipogenesis

The use of estrogens and progestogens in oral contraceptives has caused increased awareness of the effects of gonadal steroids on metabolic processes and especially on the glucose and lipid metabolism. One of the earliest metabolic effects observed was the risk of developing reduced glucose tolerance.[1, 2] It has been suggested that the women at greatest risk are those with episodes of impaired glucose tolerance, for example, during pregnancy, or those with a strong family history of diabetes.[3] However, major epidemiologic studies indicate that oral contraceptive users have more than doubled the risk of developing a deterioration in glucose tolerance compared with nonusers.[4, 5] In contrast, normal women have a very limited, if any, risk of developing clinically frank diabetes during oral contraceptive treatment.[6] During the last decades, many studies have attempted to quantify the impact of oral contraceptives on glucose metabolism, because the first

reported changes in carbohydrate metabolism were based on small metabolic studies and because the potential diabetogenic effects remain a concern to public health due to the enormous number of pill users. However, the discrete effects of sex steroids on glucose metabolism make it mandatory to ensure monitoring of the possible changes with precise and accurate measurements. The study period should not be too short, that is, at least 6 months, and the number of women included in the study sufficiently high to enable detection of the expected changes. Moreover, when studying changes in glucose metabolism, possible confounding factors exist, such as differences in nutritional habits, in addition to ethnic and circannual variations in the endogenous maintenance of glucose homeostasis. For obvious reasons not all clinical studies on the metabolic effects of oral contraceptives have been performed under ideal circumstances, but aside from methodologic problems that may be difficult to circumvent, most studies are also confined by their descriptive nature. Only a few elucidate the mechanism of action at the cellular level and the possible interrelationship between the glucose and lipid metabolic systems. This review summarizes the influence on glucose metabolism of different contraceptive steroid combinations, the possible mechanism behind a disturbance of the euglycemic state, and the concomitant impact on lipid metabolism.

Influence on glucose metabolism of high- and low-dose preparations

Early studies on the metabolic effects of oral contraceptives demonstrated consistent impairment of glucose tolerance by increases in fasting glucose and insulin levels and in the response of these variables after a glucose challenge.[1, 2, 7] Studies by Spellacy et al.[8-11] also revealed that the artificial estrogenic components used in combined oral contraceptives have little or no deteriorating influence on glucose homeostasis when administered alone, whereas progestogens, to a certain extent, were able to mimic the diabetogenic effect of the combined compounds. Since these inventive studies were published, a bulk of scientific data has become available on the undesired metabolic effects of sex steroids, but much confusion still exists on the results and their clinical interpretation. One of the reasons for the discrepancy between data from different studies is failure to discriminate between qualitative and quantitative differences between the various combined oral contraceptive compounds with identical contraceptive effect. First and foremost, a distinction should be made between preparations containing 50 μg or more of ethinyl estradiol and high progestogen content and the newer low-dose preparations with 35 μg or less of estrogen and reduced amounts of progestogen, because the impact on glucose metabolism is clearly shown to be dose dependent.[3] In addition, differences in the biochemical structure of the steroid components should be considered because the molecular configuration decides both the receptor-mediated and the direct cellular effects. In contrast to the artificial estrogens used in oral contraceptives, ethinyl and mestranol, the progestogens are represented by a variety of steroid formulations, with marked differences in their pharmacodynamic responses and classified estranes, gonanes, and pregnanes. The estrane progestogens include norethindrone acetate, lynestrenol, norethynodrel, and ethynodiol diacetate, and all these compounds must be transformed metabolically into norethindrone to become biologically active. For many years the gonanes have been represented in oral contraceptives only by norgestrel and its active component, the dextroisomer levonorgestrel, but in recent years new types of progestogens of the gonane type, such a desogestrel, gestodene, and norgestimate, have succeeded the widely used norgestrel/levonorgestrel in the combined type of oral contraceptives. Pregnanes include megestrol, chlormadione acetate, and cyproterone acetate. As opposed to estranes and gonanes, which in structure are related to the reduced form of testosterone, 19-norethindrone, the pregnanes are derivatives of 17-hydroxyprogesterone, but today cyproterone acetate, which has specific antiandrogen properties, is the only pregnane used in oral contraceptives. Thus as a consequence of the variety of progestogens, it is useful to distinguish between the categories when considering the metabolic effects. The introduction of the new generation of gonanes has, however, also made it necessary to differentiate within these types of progestogens because despite structural similarities they display differences in biologic properties.[12]

Today two important questions are, do low-dose preparations have any deleterious effects of clinical significance on glucose metabolism and are there differences in the metabolic effects between compounds depending on the type of progestogen used? Wynn and Godsland[13] reported that the incidence of impaired glucose increased steadily from 5% to 30% during treatment with low-dose monophasic ethinyl estradiol plus levonorgestrel for 36 months and significantly less influence on glucose metabolism from compounds containing norethindrone. Not all investigators[14, 15] substantiated these findings. Using a monophasic preparation of 30 μg of ethinyl estradiol and 150 μg of levonorgestrel, we found no changes in fasting glucose, insulin, or glucagon values after 2 and 6 months in healthy nondiabetic women. After hormonal intake for 6 months, the insulin response to oral glucose increased significantly, but no change was observed in glucose tolerance.[16] The introduction of triphasic ethinyl estradiol—levonorgestrel preparations was part of the strategy to reduce the metabolic side effects by reduction of the steroid dose. We examined the effect of such

a preparation in normal women and in women with previous gestational diabetes. In both groups the triphasic preparation resulted in a significantly lower insulin response to oral glucose.[17] The new "selective" progestogens of the gonane type, desogestrel and gestodene, with a high affinity for human progesterone receptors, have only been marketed for a limited period, but it appears from present investigations with both monophasic and triphasic combinations that they may have a similar effect on glucose metabolism as the monophasic ethinyl estradiol—levonorgestrel combinations, that is, a hyperinsulinemic response to oral glucose.[18] Also, intake of low-dose combined monophasic preparations containing the pregnane progestogen cyproterone acetate may result in an increased area under the insulin curve during the oral glucose tolerance test.[19] To summarize, there seems to be no risk of impairment of glucose tolerance during short-term intake of combined low-dose oral contraceptives in young normal women, but during intake of almost all preparations marketed, there have been reports of a hyperinsulinemic response to oral glucose. The short-term effects of mild hyperinsulinemia are hardly of clinical relevance, although the observation should not be ignored. Among the changes associated with aging is a decline in glucose tolerance preceded by hyperinsulinemia.[20] Thus long-term use of oral contraceptives or expanded use by women also >35 years old may modulate the physiologic change in glucose tolerance and thereby facilitate the occurrence of coronary heart disease.[21] This potential association makes it mandatory with investigations on the possible sustained effect on insulin secretion and insulin action in users of oral contraceptives.

Mechanisms of action

In nearly all investigations on the influence of oral contraceptives on glucose metabolism, the traditional glucose tolerance test has been used either intravenously or orally. Although such measurements of plasma glucose combined with simultaneous measurements of plasma insulin and eventually glucagon levels are necessary and useful when glucose intolerance is described and classified, they give insufficient information on the mechanism that underlies the disturbances in the glucose homeostasis during hormonal treatment. However, the common observation in pill users of a hyperinsulinemic response to a glucose challenge indicates a change in the important biologic balance between insulin secretion and insulin action. Pancreative hyperresponsivity is the physiologic response to impaired insulin tissue action to keep glucose tolerance normal. Therefore decrease in insulin sensitivity at the cellular level in peripheral tissues is the most obvious explanation for the influence of oral contraceptives on glucose metabolism although a change in the metabolic clearance rate of insulin in the liver may also play a role. Insulin initiates cellular action by binding to a specific glycoprotein receptor on the surface of the cell. The first direct demonstration of insulin receptors was performed more than 15 years ago, and further experiments established the relationship between the binding reaction and the subsequent changes in intracellular metabolic pathways.[22] The receptor is a tyrosine-specific protein kinase with two subunits. The α subunit binds to insulin, which causes an autophosphorylation of the tyrosine molecule of the β unit. This results in a stimulation of glucose transport across the cell membrane.

Insulin receptors and oral contraceptives. Several studies have been performed on insulin receptor binding during intake of oral contraceptives. Nearly all studies are in vitro measurements on circulating cells, first and foremost erythrocytes and mononuclear leukocytes. Most often Scatchard analyses have been applied to quantitate insulin-binding capacity and affinity. Using this technique Tsibris et al.[23] and De Pirro et al.[24] found after administraiton of monophasic compounds (ethinyl estradiol, 50 μg or 30 μg, plus 250 μg of norgestrel or 150 μg of levonorgestrel and 50 μg or 30 μg of ethinyl estradiol plus 500, 1000, or 400 μg of norethisterone) cessation of the physiologic variation of insulin receptor concentration and affinity reported earlier in the menstrual cycle. No differences in binding parameters were found between the luteal phase in the control cycle and the measurements performed during hormonal intake. We measured the influence of the triphasic ethinyl estradiol–levonorgestrel compound on insulin receptor binding to monocytes and erythrocytes in nondiabetic women and in women with previous gestational diabetes[25] to see whether the encouraging clinical results previously obtained with the same contraceptive compound[17] could be substantiated by estimations of the insulin antagonistic effects at receptor levels.

Before hormonal treatment, the women with previous gestational diabetes had significantly impaired glucose tolerance when compared with healthy control subjects, but no differences in insulin receptor binding were observed. Glucose tolerance and the insulin response to oral glucose remained unchanged in both groups during the treatment period. In control subjects a significant decrease in insulin receptor binding to monocytes was observed after hormonal intake for 6 months, whereas insulin receptor binding remained unchanged in women with previous gestational diabetes. No correlation was found between glucose tolerance and insulin receptor binding to erythrocytes and monocytes during intake of low-dose oral contraceptives.

However, studies of insulin binding to receptors on monocytes and erythrocytes are not always easily in-

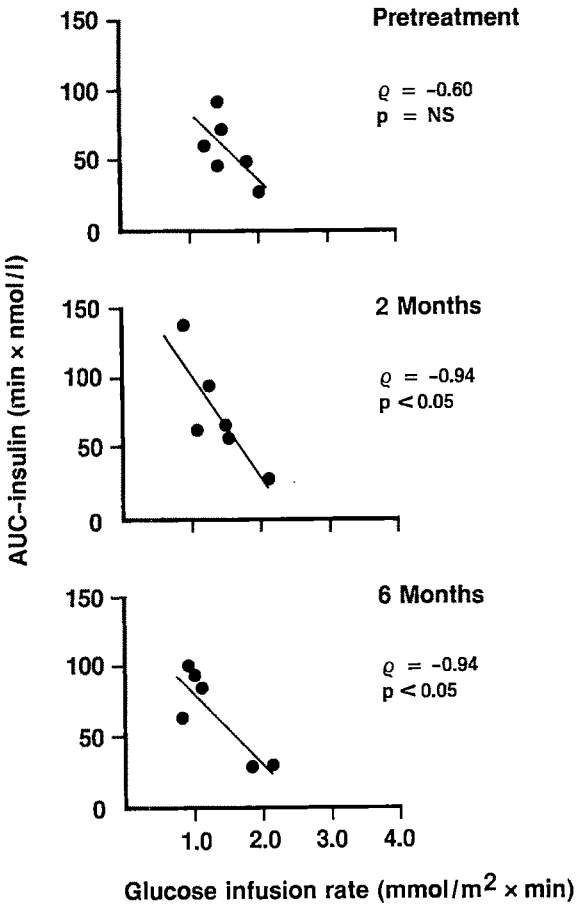

Fig. 1. Correlation between area under insulin curves *(AUC)* and glucose infusion rates during euglycemic clamp investigations in normal women ($N = 7$) receiving a low-dose oral contraceptive (ethinyl estradiol plus levonorgestrel) for 6 months.

terpretable, partly because of methodologic problems and partly because of lack of clear evidence that changes in insulin binding blood cells in humans are comparable with "true" changes in insulin-responsive tissues. Lack of correlation between measurements in erythrocytes and monocytes has been previously reported, although results from correlation studies vary. The discrepancies may be explained by the fact that erythrocytes have a highly specialized membrane that is unable to synthesize new insulin receptors and thus lack the capacity to replace insulin receptors lost during aging of the cells.

In vivo clamp investigations and oral contraceptives. Because measurements of insulin binding to blood cells in vitro do not necessarily reflect insulin receptor function in vivo and give no information on postreceptor defects, various other methods have been invented to assess insulin sensitivity. The euglycemic clamp technique[26] is one of the best because it surmounts the effect of changes in blood glucose concentration on glucose utilization. With this technique plasma insulin concentration is increased to a constant level by a primed, continuous intravenous insulin infusion. Plasma glucose is maintained at the euglycemic level by means of variable glucose infusion. After the initial insulin infusion, a quasi steady state is reached in which total glucose turnover can either be quantified by means of a (^{3}H)3-glucose infusion or calculated from the unlabeled exogenous glucose infusion by a nonequilibrium equation, provided endogenous (hepatic) glucose production is zero. The rate of glucose metabolism during the insulin infusion can be directly compared under differing physiologic conditions if the concentration of glucose-perfusing, glucose utilizing tissues is the same, that is, the arterial glucose concentrations are matched.

We assessed in vivo insulin action using the euglycemic clamp technique in women with previous gestational diabetes and in nondiabetic women before and during intake of a low-dose ethinyl estradiol–levonorgestrel triphasic oral contraceptives for 6 months.[27] Both groups had normal oral glucose tolerance tests and plasma insulin levels before and during treatment. The glucose metabolic clearance rate and endogenous glucose production were calculated from specific glucose activities. The rates of glucose metabolized during the investigation were similar in both groups before treatment. During hormonal intake the rate of glucose metabolized decreased significantly (27%) in women with previous gestational diabetes, whereas the decrease in normal subjects was less pronounced (17%). Moreover, in the group of normal women, there was a significant negative correlation between glucose uptake during the clamp investigation and the area under the insulin curves calculated from a glucose tolerance test preceding the clamp investigation (Fig. 1). Such a correlation was not found in previous gestational diabetic women, indicating that normal women are perfectly capable of compensating for increased insulin resistance during hormonal intake, whereas the insulin secretion in the previous diabetic women is slightly impaired.

Thus the study showed that in normal women and women with previous gestational diabetes, intake of oral contraceptives may decrease insulin sensitivity, although no change in oral glucose tolerance can be observed. To date only one other clamp study on insulin sensitivity in normal women receiving oral contraceptives has been published. Kasdorf and Kalkhoff[27] applied a euglycemic clamp in seven normal women receiving a low-dose monophasic combination of ethinyl estradiol plus levonorgestrel. After 3 and 6 months a hyperinsulinemic response to oral glucose was observed during oral glucose tolerance tests which is similar to our observations with the same compound.[16] Also, these investigators found a decrease in glucose utilization

rates, expressing decreased insulin sensitivity after steroid intake for 3 months. However, in contrast to our findings, reduced insulin sensitivity in peripheral tissue ameliorated with time and returned to baseline levels after 6 months.

Comment

This review has characterized the current state of knowledge of the influence of oral contraceptives on glucose metabolism at the cellular level. The metabolic effects are unlike other adverse reactions to drugs, insidious, and thus may be unnoticed by both patients and clinicians. However, even discrete changes in glucose metabolism may promote development of coronary heart disease as already discussed. This can partly be explained by the positive correlation between insulin resistance and partly by the influence of hyperinsulinemia on lipid metabolism.[28] Lipid changes associated with hyperinsulinemia are increased total cholesterol and triglycerides and decreased high-density lipoprotein cholesterol values.[29] The effect of hyperinsulinemia on lipid metabolism at the cellular level can be elucidated by results from animal experiments on key enzymes in lipogenesis and lipolysis.[30] Lipogenesis increases because of increased activity of glucose-6 phosphate dehydrogenase, malic enzyme 3-hydroxyacyl-Co A, whereas the activity of the glycolytic enzymes, such as phosphofructokinase, hexokinase, pyroyate kinase, and α-glycerophosphate are unchanged. In addition to inhibition of lipolysis and synthesis of cholesterol, phospholipid and triglyceride exposure of arterial tissue to insulin results in proliferation of smooth muscle cells. More long-term exposure to high concentrations in insulin results in the development of lipid-filled lesions, fatty streaks, which are similar to those seen in early atherosclerosis.[31] These findings indicate the need for long-term integrated studies on glucose and lipid metabolism if the tendency toward more widespread use of oral contraceptives in women >35 years old becomes more manifest. In young healthy women there is no reason to believe that the modern types of combined low-dose oral contraceptives will have any influence on glucose metabolism that will result in any clinical problem.

Low-dose oral contraceptives and carbohydrate metabolism

Ian F. Godsland, BA, David Crook, PhD, and Victor Wynn, MD, FRCP, FRCPath
London, England

Combined oral contraceptive use has been associated with increased incidence of impaired and diabetic glucose tolerance. Although increased risk of overt symptoms of diabetes has not been associated with oral contraceptive use, increased risk of coronary heart disease has been consistently demonstrated. Diabetes is associated with increased risk of coronary heart disease, especially in women. Elevated plasma glucose and insulin concentrations are also associated with increased risk of coronary heart disease. Studies of the effects of low-dose oral contraceptives on glucose tolerance test plasma glucose and insulin levels are reviewed. Low-dose combined oral contraceptives induced changes in measures of carbohydrate metabolism in directions consistent with increased risk of coronary heart disease. The magnitude of these changes may depend on the dose and type of progestogen. The clinical implications of these changes are unknown, but it would seem advisable to minimize them where possible. (Am J Obstet Gynecol 1990;163:348-53.)

Key words: Combined oral contraceptive, glucose tolerance, insulin, coronary heart disease

When oral contraceptive–induced deterioration in glucose tolerance was observed in the mid-1960s, there was concern that this might increase the risk of diabetes mellitus in oral contraceptive users.[1] Subsequently, major population studies have demonstrated increased prevalence of diabetic oral glucose tolerance tests among oral contraceptive users. In the Walnut Creek Contraceptive Drug Study, there was a 2.0% prevalence of diabetic oral glucose tolerance tests among oral contraceptive users compared with a 1.0% prevalence in nonusers.[2] In the 1976 to 1980 U.S. National Health and Nutrition Examination Survey, there was a 1.7% prevalence among oral contraceptive users compared with a 0.6% prevalence among nonusers.[3] Furthermore, these studies also demonstrated that the prevalence of impaired glucose tolerance was increased more than twofold in oral contraceptive users. Both studies used National Diabetes Data Group criteria for defining diabetes mellitus and impaired glucose tolerance. However, although diabetic and impaired glucose tolerance test profiles have been consistently demonstrated in oral contraceptive users, increased prevalence of overt symptoms of diabetes mellitus has not been observed.[4] Consequently, there has been a tendency for the importance of studies of carbohydrate metabolism in oral contraceptive users to be overlooked. The absence of an association between clinical symptoms of diabetes mellitus and oral contraceptive use may derive from the relatively short duration of follow-up and the young age of the women included in existing epidemiologic studies. Diabetes associated with oral contraceptive use might be expected to develop over a long period in response to sustained deterioration in glucose tolerance and thus may be seen as a past-user effect in older, postmenopausal women. Thus an effect might be seen in modulation of the age-related risk of maturity onset diabetes.

Although the risk of diabetes mellitus associated with oral contraceptive use remains to be effectively explored, the risk of coronary heart disease, as evidenced by myocardial infarction, has been consistently demonstrated. Sixteen studies have shown that oral contraceptive use increases the risk of fatal or nonfatal myocardial infarction either independently or by poten-

tiating the effects of other risk factors.[5-20] Only two studies have shown no evidence of increased risk.[21, 22] There is also increased risk of coronary heart disease with diabetes mellitus and impaired glucose tolerance.[23-35] Thus the questions arise—could the effects of oral contraceptives on carbohydrate metabolism contribute to the increased risk of coronary heart disease associated with oral contraceptive use? How relevant are these potential associations, established in users of older high-dose oral contraceptives, to current low-dose oral contraceptives?

Carbohydrate metabolism and coronary heart disease

Increased mortality rates in diabetic persons are primarily the result of vascular disease. The risk of coronary heart disease in diabetic persons has been demonstrated in several prospective studies.[23-28] Interestingly, in all except one,[24] diabetic women were at greater risk than diabetic men. Impaired glucose tolerance, which is defined either by established criteria or by the upper percentiles of oral glucose tolerance test glucose concentrations in the cohort under examination, has also been found to be associated with increased risk of coronary heart disease.[29-33] Two such studies have included both men and women, and both showed that women were greater risk than men.[27, 29] Thus although the risk of coronary heart disease with impairment of glucose tolerance has not been as thoroughly studied in women as in men, the few studies that have been carried out suggest that women are at increased risk, perhaps more so than men.

Elevated glucose concentrations may be only a marker for risk of coronary heart disease, or they may be causally related to the development of the pathologic changes underlying coronary heart disease. Glycosylation of apolipoprotein B has been shown to interfere with the catabolism of low-density lipoprotein and the inhibition of cholesterol synthesis by low-density lipoprotein.[34, 35] Thus there are theoretic mechanisms by which deterioration in glucose tolerance could promote atherogenesis and coronary heart disease. A complicating factor, however, is whether the deterioration in glucose tolerance in the epidemiologic studies described is associated with insulin deficiency or insulin excess. In oral contraceptive users deterioration in glucose tolerance has consistently been associated with insulin excess.[36-38] Three studies have examined both insulin and glucose as risk factors for coronary heart disease. The Helsinki Policemen Study of 982 men, ages 35 to 64 years, showed a significant relationship between 9.5-year coronary heart disease incidence (death or nonfatal myocardial infarction) and plasma insulin concentration at 1 and 2 hours after an oral glucose load.[32] The association remained after multivariate analysis. Neither fasting plasma insulin or any of the plasma glucose measures were related to coronary heart disease risk. The Paris Prospective Study of 7038 men, ages 43 to 54 years, showed a significant relationship between 11.2-year coronary heart disease mortality and fasting plasma insulin and plasma insulin concentrations 2 hours after an oral glucose load.[31] In a multivariate analysis only the fasting plasma insulin concentration remained a significant risk factor. The Busselton Study is the only prospective study that examined insulin as a risk factor in both men and women.[29] In this study the 1-hour insulin concentration after an oral glucose load was significantly associated with 6-year incidence of coronary heart disease, 12-year coronary heart disease mortality, and 12-year cardiovascular disease mortality, but only in men, ages 60 to 69 years. Insulin was not a risk factor in younger or older men or in women. However, the 1-hour blood sugar level was significantly related to coronary heart disease and cardiovascular disease mortality in women, ages 60 to 69 years, but not in younger or older women or men. When the 12-year mortality from cardiovascular disease was examined in men and women older than 60 years, there was increasing risk with increasing 1-hour blood sugar and plasma insulin concentrations in men, but only with increasing 1-hour blood sugar level in women. The Busselton Study differs from the Helsinki and Paris studies in that it did not find insulin to be a risk factor for coronary heart disease in men less than 60 years old. The study also differs because it used a lower dose of glucose (50 gm versus 75 gm) for the oral glucose tolerance tests and thus may have been less sensitive to distinguishing variations in insulin response.

The role of insulin as a risk factor for coronary heart disease in women requires further investigation. It is perhaps relevant that in the Framingham Study, which clearly demonstrated that diabetic women are at greater risk of coronary heart disease than are men, almost all women with coronary heart disease took insulin.[23] On the basis of a multivariate analysis of this study, including blood pressure, smoking, and serum cholesterol, they concluded that other factors, as yet unknown, would be needed to account for the higher incidence of cardiovascular disease in diabetic persons. Insulin levels were not included in the multivariate analysis.

The potential role of insulin in atherogenesis has recently been reviewed.[39] Insulin has been shown to promote arterial smooth muscle cell proliferation, stimulate cholesterol synthesis in smooth muscle cell, induce lipid-containing lesions in the arteries of animals fed a normal diet, and augment lipid synthesis in arteries. Arteries also contain receptors specific for the growth-promoting effects of insulin. Thus insulin can be di-

Table I. Low-dose combined oral contraceptive formulations currently in use in the United Kingdom

Formulation	*Code*	*United Kingdom proprietary name*
250 μg levonorgestrel + 30 μg ethinyl estradiol	250LG:30EO	Eugynon-30, Ovran-30

75 μg gestodene + 30 μg ethinyl estradiol	75DG:30EO	Femodene, Minulet
50/75/125 μg levonorgestrel + 30/40/30 μg ethinyl estradiol	50-125LG:30-40EO	Logynon, Trinordiol
500/750/1000 μg norethisterone + 35 μg ethinyl estradiol	500-1000NE:35EO	Trinovum

rectly involved in some of the processes that typically accompany atherogenesis.

Insulin excess will be associated with an inadequate tissue response to insulin, that is, insulin resistance. Reaven[40] and Zavaroni et al.[41] have recently drawn attention to the possible importance of insulin resistance in coronary heart disease risk. Insulin resistance is associated with numerous disturbances that have consistently been linked with increased risk of coronary heart disease. These include impairment of glucose tolerance, hyperinsulinism, elevated very low–density lipoprotein triglyceride concentrations, reduced high-density lipoprotein cholesterol concentrations, and hypertension. The term "syndrome X" has been introduced to encompass this range of disturbances. Whether insulin resistance is primary in the development of coronary heart disease or whether it is an accessory to other predisposing factors remains to be determined.[42] Effective research in this area will depend on the application of techniques that enable accurate quantification of insulin resistance, and several alternatives, including the glycemic clamp and mathematical modeling of glucose tolerance test glucose and insulin concentrations, are now available.[43]

Thus there is evidence that both elevated glucose and insulin concentrations can have direct effects that could further atherogenesis. When elevations in glucose and insulin occur together, they indicate resistance to the action of insulin, which may underly a number of important metabolic changes that indicate increased risk of coronary heart disease. As yet, we have no reason to believe that oral contraceptive–induced insulin resistance with its accompanying elevations in glucose and insulin concentrations is entirely innocent with regard to atherogenesis and coronary heart disease. As in many aspects of coronary heart disease research, the risk in women relating to impairment of glucose tolerance and elevated insulin levels has been inadequately investigated. Although such uncertainty exists, it would seem prudent to clearly define the effects of different oral contraceptive formulations on glucose and insulin levels and favor those that have the least potentially adverse effects on these measures.

Low-dose oral contraceptives and carbohydrate metabolism

A rough distinction may be made between the three eras of oral contraceptives. In the 1960s, the high-dose oral contraceptives containing >50 μg of estrogen predominated; in the 1970s, there were medium-dose oral contraceptives containing 50 μg of estrogen; and in the 1980s, there have been the low-dose oral contraceptives containing <50 μg of estrogen. Two additional developments occurred during the low-dose era, namely, the introduction of phasic oral contraceptives and the introduction of novel progestogens designed to have minimal androgen-like side effects. Some of the most commonly encountered low-dose oral contraceptives are listed in Table I.

In a review of studies of the effects of oral contraceptives on carbohydrate metabolism until 1980, Furman[36] noted that most have shown that high- and medium-dose oral contraceptives could impair glucose tolerance and induce a hyperinsulinemic response to glucose. The effects of low-dose oral contraceptives on glucose and insulin levels have been the subject of sporadic reports, from which it is difficult to obtain a consistent picture. Findings from those studies of normal women taking low-dose oral contraceptives, published in the 1980s and for which oral glucose tolerance test glucose and insulin data were given, are summarized in Table II. Where possible, the incremental area (i.e., the area under the concentration profile but above the basal level) has been used to provide a measure of disturbance in oral glucose tolerance test response unconfounded by changes in the fasting state. All these studies were longitudinal in design, and women acted as their own controls. Almost all claimed that the formulations studied had no effect on carbohydrate metabolism. This is rather surprising when one considers the magnitude of the changes that many observed. For example, two studies[52, 53] conclude that a

*Spellacy et al. summarized studies of this formulation carried out during the 1970s. These showed variable effects on glucose tolerance but a consistently elevated insulin response.

†Percentage change could not be calculated; published figures given.

norethindrone-containing triphasic oral contraceptive had no effect on carbohydrate metabolism. Nevertheless, the increases in incremental area under the oral glucose tolerance test glucose concentration profile were 73% and 65%, respectively. In contrast, in a large cross-sectional analysis of oral glucose tolerance test glucose and insulin responses (648 nonuser controls compared with 239 users of a low-dose levonorgestrel-containing oral contraceptive), we have found that a percentage difference of 35% in oral glucose tolerance tests incremental glucose area was highly significant.[54] However, the importance of our study lay in the additional observation that underlying the relatively small, albeit significant, differences in mean incremental glucose and insulin areas were differences in the frequency distribution of oral glucose tolerance test glucose and insulin responses between oral contraceptive users and nonusers that were comparable with differences seen between those at risk of coronary heart disease and those not at risk. Therefore it is not sufficient to conclude on the basis of 10 or 20 patient studies, that if no changes in the oral glucose tolerance test glucose response occurred outside the normal range, there were no important effects on carbohydrate metabolism.

The magnitude of the effects on glucose and insulin levels reported in many studies that claim no effect of low-dose oral contraceptives on carbohydrate metabolism must raise questions about the power of their design. Furthermore, with the exception of the study of van der Vange et al.,[45] no studies have attempted a comparative evaluation of the wide range of low-dose oral contraceptives currently available. In the recently completed study by our group,[55] 1127 women each re-

ceived an oral glucose tolerance test with measurement of plasma glucose, insulin, and C-peptide. Users of five monophasic- and two triphasic-combined oral contraceptives and two progestogen-only oral contraceptives were included in the study. Combination oral contraceptives contained an average estrogen dose of 30 to 35 μg and thus differed primarily in the progestogen content. In the combined oral contraceptive groups, the glucose and insulin responses during the oral glucose tolerance tests were significantly higher than among the control subjects. These differences remained after standardization for age and weight and selection of control groups for each oral contraceptive group, which did not differ significantly in cigarette smoking, alcohol intake, exercise habit, family history of diabetes or heart disease, and the time period over which testing was carried out. Furthermore, there was a consistently observed effect of progestogen dose on the glucose and insulin response. Levonorgestrel- and norethindrone-containing oral contraceptives each contained identical doses of estrogen, but a low or high progestogen dose. Although relative differences were small, the higher progestogen dose had the greatest impact in every case. There was also a trend depending on the type of progestogen. Among the monophasic oral contraceptives the levonorgestrel-containing formulations had the greatest impact, followed by the norethindrone- and desogestrel-containing formulations. With the exception of the high-dose levonorgestrel formulation, in which there was a relatively low response, the C-peptide concentration responses confirmed the relative differences in insulin response and demonstrated that underlying the elevated insulin levels were increases in pancreatic insulin secretion. Furthermore, the relative impact of the different oral contraceptives on carbohydrate metabolism paralleled the relative impact on measures of lipid metabolism. This study suggests that there may be coordinated changes throughout a range of metabolic variables in response to low-dose oral contraceptives, with the magnitude of these changes depending on the dose and type of progestogen.

We conclude that even with the introduction of low estrogen doses, phasic formulations, and new progestogens, the impact of combined oral contraceptives on carbohydrate metabolism remains an important issue. Future studies will need to pay particular attention to the statistical power and the population from which the study group is drawn and will need to incorporate several different formulations to make effective comparisons. Evaluation of a wide range of metabolic changes will be required in each study, for example, changes in lipoproteins and measures of hemostasis. As long as uncertainty remains over the implications of these effects for risk of diabetes mellitus and coronary heart disease, it will be necessary to evaluate thoroughly the metabolic impact of each oral contraceptive and develop formulations or regimens that minimize this impact.

Some aspects of the relationship between oral contraceptives, lipid abnormalities, and cardiovascular disease

Göran Samsioe, MD, PhD, and Lars-Åke Mattsson, MD, PhD
Göteborg, Sweden

Most epidemiologic studies suggest an association between current use of combined oral contraceptives and certain manifestations of cardiovascular disease. Most of the data relate to older preparations little used today. Decreased levels of high-density lipoprotein cholesterol and increased amounts of low-density lipoprotein cholesterol were common findings with the older formulations. More recent experimental and epidemiologic data suggest that the potential risk of cardiovascular disease in oral contraceptive users is hardly predicated on an arteriosclerosis basis but related more to thromboembolic events. Because changes in the serum lipid profile are often associated with alterations in the factors of hemostasis, it seems reasonable to suggest the use of preparations void of profound changes in lipid metabolism, especially when other means of efficacy are available inclusive of the newer low-dose oral contraceptives. When risk factors for cardiovascular disease are present, determination of total cholesterol is desirable. In subjects with elevated serum cholesterol, a serum lipid profile should be determined. A woman at risk of cardiovascular disease should be carefully monitored, and repeated lipid determinations are recommended. (Am J Obstet Gynecol 1990;163:354-8.)

Key words: Oral contraceptives, cardiovascular disease, serum lipids

It is well established that certain abnormalities in lipid and lipoprotein metabolism are linked to increased events of cardiovascular disease (CVD). In this respect, most epidemiologic data emphasize high levels of low-density lipoprotein (LDL) and low levels of high-density lipoprotein (HDL). In addition, data suggest the corresponding apolipoproteins, that is, apolipoprotein B for LDL and apolipoprotein A_1 and A_2 for HDL, behave in a similar manner. Combinations of these abnormalities might further augment the risk of CVD.

In general serum cholesterol levels have also been documented to have a clear relationship with CVD, and pharmacologic lowering of cholesterol has resulted in decreased events of CVD at least in men.[1, 2] Accumulating evidence also suggests serum triglycerides as an important risk factor in women.[3, 4] Data from Framingham imply that triglycerides constitutes a risk factor only in women with low HDL cholesterol levels (Fig. 1).[5] In most nonpharmacologic conditions, very low–density lipoprotein (VLDL) and HDL display an inverse relationship. Oral administration of estrogens elevates both VLDL and HDL, and progestogens tend to have opposite effects. Pharmacologically induced alterations in which VLDL and HDL move in the same direction are more difficult to interpret as a function of risk of CVD. Further data on this issue seem highly warranted.

Several other risk factors for CVD have been identified. Sex, age, ethnic group, and family history cannot be influenced, whereas others are potentially changeable. Among such factors one finds smoking, blood pressure, obesity, diet, and sedentary life-style. Some of these risk factors also comprise serum lipid abnormalities, as well as smoking and obesity. In addition, a number of chronic diseases, for example, diabetes, have also been identified as risk factors. The combination of two or more risk factors increases the risk almost exponentially. Therefore it is not surprising that cardiovascular events in oral contraceptive (OC) users are less uncommon in elderly obese or smoking women and that the incidence of CVD varies throughout the world as indicated by a World Health Organization study.[6]

CVD could principally follow from two different mechanisms. Deep venous thrombi could be formed as a result of changes in the coagulation cascade, and emboli from a thrombus may cause a sudden event.

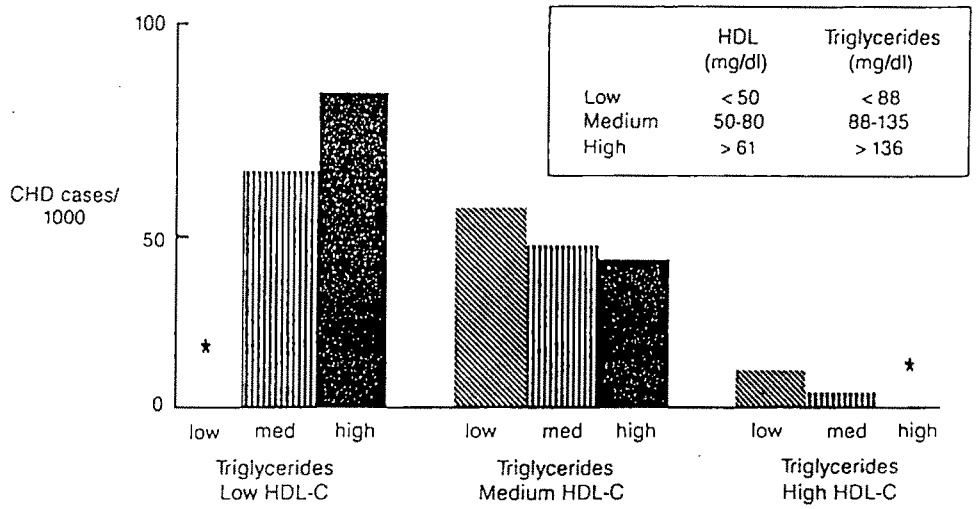

Fig. 1. Incidence of coronary heart disease *(CHD)* in relation to levels of HDL cholesterol *(HDL-C)* and triglycerides. *Groups with <86 persons at risk. (From Castelli WP, et al. Am Heart J 1986;112:432-7.)

Table I. Percent changes in cholesterol and triglycerides in serum, that is, total, and in HDL and LDL after oral medication with unopposed EE; figures are adjusted for sample size, duration of study, and pretreatment endocrine situation

	Dose (μg)	*Studies*	*Change in*			
			Cholesterol			*Triglycerides*
			Total	*HDL*	*LDL*	*Total*
EE	10	2	−12	+5	−12	+30
	20	3	−7	+18	−15	+66
	30	1	−11	+22	−20	+71
	35	1	−6	+16	−12	+68
	50	3	+1	+28	−16	+70

Pertinent evidence also suggests an association between coagulation factors and serum lipid constituents. Hypertriglyceridemia frequently accompanies high levels of fibrinogen and factor X, as well as low fibrinolytic activity.[7] In vitro studies suggest further that increasing concentrations of cholesterol promote platelet aggregation.[8]

A second mechanism by which CVD can occur is by way of atherosclerosis. Vascular lesions could exist before OC medication or develop during OC use as a result of the aging process or even enhanced by OC use, possibly by way of changes in lipid metabolism or alterations induced in the vessel wall.

OC medication induces ovulation inhibition, which almost abolishes endogenous ovarian steroid production. Early menopause, natural or surgical, has been shown to be associated with an increased risk of CVD and alterations in lipid metabolism. It cannot be ruled out with certainty that lack of endogenous steroids has no role in the development of CVD in OC users. Contraceptive steroids given to women undergoing oophorectomy may help distinguish this mechanism further.[9] In principle ethinyl estradiol (EE) tends to increase plasma content of cholesterol, as well as triglycerides, phospholipids, and apolipoproteins. This is reflected in serum lipoproteins as increased levels of HDL and VLDL and at higher doses of LDL. A similar pattern is observed during pregnancy. Lower doses of estrogens, including EE, and early pregnancy seem to decrease LDL levels, but HDL and VLDL are still augmented. However, in all examples, the HDL/LDL cholesterol ratio is above 1 compared with normally menstruating women in whom the ratio is slightly below 1.[10]

EE differs from natural estrogens especially in its ability to augment triglycerides (Table I). This may imply a more marked inhibition of hepatic lipase by the alkylated estrogen. This enzyme is also involved in HDL turnover as exemplified by its importance in the removal of HDL_2 particles from plasma. After EE, triglycerides are elevated not only in VLDL but also substantially in LDL and HDL. In contrast to natural es-

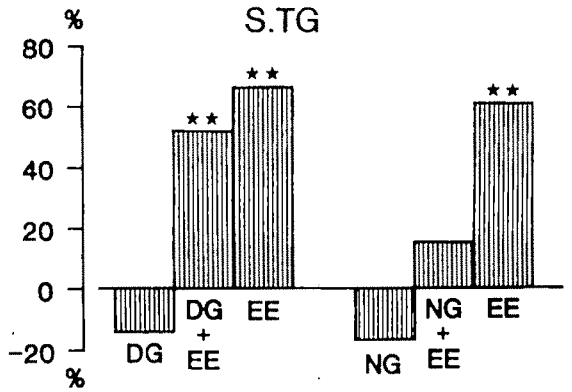

Fig. 2. Percent change in serum triglyceride *(STG)* levels after administration of two 19-nor teststerone derivatives, (*DG*, Desogestrel; *NG*, levonorgestrel) 150 μg/day, orally, in combination with 30 μg of EE and after EE alone (30 μg).[13]

trogens and normal pregnancy, alterations in the molar composition of lipoprotein particles seem to be more marked after EE. This renders the use of Friedwald's formula more difficult because serum triglyceride levels influence the calculation of LDL cholesterol.[11]

It is difficult to assess if the differences observed between EE and natural estrogens should be ascribed the chemical dissimilarity or are merely functions of differences in receptor interactions or pharmacokinetic and pharmacodynamic behavior.

Because all commercially available OCs contain EE (or its methyl ether, mestranol, which is rapidly converted to EE), the differences in lipid metabolic response must be the result of the amount administered and the type and dose of the corresponding progestogen. Lipid metabolic effects by progestogens in OC users could either be androgenic, antiestrogenic, or possibly progestogenic. So far it has been difficult to demonstrate clearly any lipid metabolic effects solely because of effects mediated by way of the progestogen receptor.[12] Because all progestogens downregulate the quantity (and quality?) of estrogen receptors, an antiestrogenic effect is common in all progestogens. Androgenicity has also been demonstrated to be most pronounced for the older 19-nor testosterone derivatives, norethisterone and levonorgestrel, but less so for 17-alpha-hydroxy progestogens and the newer 19-nortestosterone derivates, such as desogestrel, gestodene, and norgestimate. Antiestrogenic effects by progestogens require the simultaneous presence of an estrogen. In studies of women having oophorectomy, levonorgestrel, desogestrel, and cyproterone acetate have similar effects on, for example, serum triglycerides when given alone. However, in combination with the corresponding estrogen as in commercially available OCs, obvious dissimilarities can be amply demonstrated (Fig. 2).

A possible explanation is the differences in antiestrogenicity by the three progestogens. Nonetheless, the concentration of hormone receptors in the liver cannot readily explain the marked effects on liver-derived serum constituents as influenced by exogenous sex steroids. A nonreceptor or nongenomic-mediated effect must also be postulated, such as inhibition or activation of existing hepatic enzyme systems.[12]

In the so-called Royal College of General Practitioners Study,[15] increasing the dose of norethisterone or levonorgestrel seemed to increase the number of CVD events despite the constant dose of the corresponding EE. It was an intriguing thought at the time to compare these data on arterial disease with those obtained from the same preparations on HDL cholesterol. However, several later observations indicated that it was too simple an analogy.

Nonetheless, this observation focused on the progestogen component as also being at least partly responsible for arterial disease and provoked enhanced interest in the development of new progestational agents with higher selectivity and sensitivity for the progestogen receptor. Desogestrel seems to differ from levonorgestrel particularly in its antiestrogenic activity,[13] and rather, preparations containing desogestrel or gestodene increase HDL and decrease LDL. Long-term epidemiologic data on CVD with these preparations are to date unavailable.

Modern prescribing routines and avoiding smoking have made arterial disease in pill users a rare event, which renders epidemiologic studies difficult if aimed at describing the differences between various low-dose preparations.[15]

If cardiovascular events were mediated solely by an atherosclerotic process, possibly as a result of low HDL and high LDL, increased risk should develop after prolonged use. However, this was not the case in the Royal College of General Practitioners Study.[16] In addition, one would expect a higher incidence of CVD in former users. This too has not been verified.[17] Because arteriosclerosis is a rather slow process that develops over years, a sudden event, such as a myocardial infarction or stroke, is commonly preceded by symptoms such as angina pectoris or transient ischemic attack in subjects with an arteriosclerotic platform for their manifestation of CVD. There is no evidence to suggest that the use of OCs influences the incidence or prevalence of angina pectoris.

In a recent study on monkeys in which HDL was reduced by OCs and they were given an atherogenic diet, no excess cardiac atherosclerosis was found when compared with control animals.[18]

In a recent epidemiologic report covering mortality among OC users from 1977 to 1982, Porter et al.[15] observed 11 deaths from CVD in the nonuser group,

Table II. Tentative schedule for screening of OC users regarding cardiovascular disease if family history indicates presence of risk factors for CVD, serum total cholesterol should be assessed, if elevated, a serum lipid profile is performed, which may show a CVD risk pattern, if after 6 months use of OCs this pattern has not improved, an alternate contraceptive method should be considered

New lipid profile 6 months		
	Annual follow-up	
No change or reduced	Increased	
Annual follow-up	Reconsider contraceptive method	

STG, Serum triglycerides; *S-CHOL,* serum cholesterol.

whereas no deaths occurred among users. If the experimental data on lipid metabolism achieved by use of the newest formulations also hold true for the outcome of CVD, it would seem pertinent to suggest that as with postmenopausal replacement therapy, OC use would also protect from CVD, provided that the person is a nonsmoker.

Indeed, a study from Finland[19] implies such a possibility, and the ongoing epidemiologic study from Oxford, England,[20] points in this direction. Clearly, more evidence is needed before any firm position can be taken in regard to newer formulations of OCs and their interrelations with CVD. It should also be pointed out that during the 1960s, OCs were given to women in whom a pregnancy was highly undesirable and therefore often included women at risk of various diseases and of low socioeconomic status. Today other means of efficacious contraception are available, and women with potential risk factors are less likely to be prescribed an OC. For this reason these subjects are more prone to be found among the controls in modern epidemiologic studies on OCs, whereas the opposite was probably true during the 1960s.

It seems prudent that the use of OCs is not associated with any major risk of arteriosclerosis. Nonetheless, formulations with a "negative" influence on HDL and LDL should possibly be avoided. Even if the "atherogenic" lipoprotein pattern is of less relevance for the development of arteriosclerosis in OC users, it does indicate an altered metabolic situation that possibly can be avoided with the use of newer formulations. As previously indicated, lipid metabolic variables are also linked to hemostasis. This also includes prostacyclin and thromboxane A_2. So far data on thromboxane B_2 and 6-keto prostaglandin $F_{1\alpha}$, which are the stable metabolites of thromboxane A_2 and prostacyclin, are inconclusive in regard to the influence by OCs. However, it has been shown repeatedly[21, 22] that both estrogens and progestogens as components of OCs influence the relative content of prostaglandin-precursor fatty acids.

On the basis of current literature, a lipid screening of all potential OC users cannot be recommended. When family history suggests the presence of risk factors for CVD, serum total cholesterol should be determined. If it is elevated, a serum lipid profile should be obtained consisting of fasting serum cholesterol triglycerides and HDL cholesterol. This approach allows the estimation of LDL cholesterol according to Friedwald's formula.

If an OC is prescribed to a woman with risk factors, total cholesterol should be checked annually. If elevated cholesterol is present before OC use, a serum lipid profile should preferrably be carried out after 6 to 8 months and then annually (Table II).

Estrogenic effect of gestodene- or desogestrel-containing oral contraceptives on lipoprotein metabolism

Jan A. Gevers Leuven, MD, PhD,[a] Marianne C. Dersjant-Roorda,[b] Frans M. Helmerhorst, MD, PhD,[b] Rinse de Boer, MD,[c] A. Neymeyer-Leloux, MD,[c] and Louis Havekes, PhD[a]

Leiden and Hertogenbosch, The Netherlands

In a randomized comparative study, changes in lipoprotein metabolism during the use of two low-dose oral contraceptives with similar doses of ethinyl estradiol but with different progestogenically active compounds were evaluated for their effective estrogen/androgen balance. Sixty-eight healthy women who did not take hormonally active drugs or were pregnant the previous 3 months took either 75 μg of gestodene + 30 μg of ethinyl estradiol or 150 μg of desogestrel + 30 μg ethinyl estradiol during 12 cycles. During the first three cycles serum levels of the following parameters increased: triglycerides, cholesterol in high-density lipoprotein, and apolipoproteins A_1, A_2, and B. Additional increase was observed in apolipoprotein B only after three and six cycles. The induced changes were not significantly different in the two groups, and the levels generally remained within normal limits. The changes seen with both pills reflect a mild estrogenic dominance. On the basis of current knowledge, moderately altered lipoprotein metabolism is not expected to impose an extra risk of atherosclerosis. (AM J OBSTET GYNECOL 1990;163:358-62.)

Key words: Gestodene, lipoproteins, oral contraceptives

High plasma levels of low-density lipoprotein (LDL) cholesterol[1] and its apolipoprotein B[2] and low levels of high-density lipoprotein (HDL) cholesterol[3, 4] and its apolipoproteins A_1 and A_2[5-7] are associated with an increased incidence of ischemic heart disease. LDL is a direct cause of atherogenesis, but the role of HDL in this process is still uncertain. Thus changing LDL levels by intervention will probably alter cardiovascular prognosis, and changing HDL levels will possibly alter cardiovascular prognosis.

Women have a sixfold lower incidence of myocardial infarctions than do men by age 50 years.[8] This advantage declines thereafter. It is conceivable that this advantage is due to the effects of estrogens on lipoprotein metabolism. Postmenopausal oral estrogen therapy is indeed associated with a reduced risk of myocardial infarction,[9] and this therapy causes a decrease in LDL cholesterol[10] and an increase in HDL cholesterol.[11] However, it is also conceivable that testosterone exerts a harmful effect on cardiovascular prognosis in men ("male disadvantage"). Androgens have an HDL cholesterol–lowering effect.[12] Thus HDL levels reflect the balance of estrogenic/androgenic effects (es-

trogen/androgen balance). Progestogens can have antiestrogenic or androgenic effects,[13-15] depending on the particular biologic test model. This implies that progestogens may modify the estrogenic effects of ethinyl estradiol and may also influence the estrogen/androgen balance in oral contraceptive (OC) preparations.

We applied these principles to the effects of two OCs with the same dosage of estrogen but with a different progestogenic compound.

Methods

Subjects. Sixty-eight healthy women, ages 20 to 35 years, not pregnant or taking OCs for at least 3 months, were randomly allocated into two groups receiving either 75 μg of gestodene + 30 μg of ethinyl estradiol (GTD-EE) or 150 μg of desogestrel + 30 μg of ethinyl estradiol (DSG-EE). Fasting blood samples for lipoprotein lipid and apolipoprotein determinations were obtained during the pretreatment period and after 3, 6, and 12 cycles, between the eighteenth and twenty-second day of the cycle, between 8:00 AM and 10:00 AM.

Informed consent was obtained. The Committee on Medical Ethics of the University of Leiden approved this study.

Serum lipid levels were determined by standard methods. LDL cholesterol was calculated according to Friedewald.[16] Apolipoproteins A_1 and A_2 were determined according to Cheung and Albers[17] and LDL apolipoprotein B according to Havekes et al.[18]

Statistics. To test for significant difference from zero, the Student *t* test for paired (for changes within group) and unpaired observations (for differences between groups) was used when the results were normally distributed. Otherwise, the Wilcoxon rank test and Mann-Whitney U test were used, respectively.

Results

Eight subjects did not complete this study. The reason for dropping out was not related to the use of OCs.

Table I shows the effects on the serum levels of (lipoprotein) lipids and apolipoproteins during OC use. Between the first three cycles, a significant increase in triglyceride levels was noted in both OC groups. After the third cycle, no further increase in triglyceride levels was found. Triglyceride levels in the two groups were

not significantly different in the four periods of observation.

LDL cholesterol values did not increase during use of these OC preparations; in the DSG-EE group even a slight but significant decrease was found during the first three cycles, although this effect became nonsignificant during the following cycles. The HDL values increased significantly during the first three cycles in both groups—by 14% in the GTD-EE group and by 7% in the DSG-EE group. No further change in these values after three cycles was observed until 1 year. In all four periods of observation no significant difference was found between the two groups in LDL and HDL cholesterol levels. In Table II the effects on serum apolipoprotein levels are shown. The baseline levels in the two groups were in good agreement with each other, except for apolipoprotein A_2, which was significantly higher in the DSG-EE group. A highly significant increase in all apolipoproteins was found during the first three cycles of OC use in both groups. After the third cycle LDL apolipoprotein B but not apolipoprotein A_1 and A_2 increased further in both groups. The increase in apolipoprotein B was significant during each period of observation and is shown in more detail in Fig. 1. The range in percentage change in LDL apolipoprotein B between the twelfth cycle and the pretreatment period was 1% to 69% in the GTD-EE group and −11% to 85% in the DSG-EE group. At the sixth cycle a dip in the apolipoprotein A_2 pattern occurred in the GTD-EE group. Except for apolipoprotein A_2 levels at the end of the sixth cycle, no difference in the effect of the two OC preparations on apolipoprotein levels was found.

As shown in Table III, the composition of the lipoproteins appeared to change in LDL only, that is, an apparent depletion of cholesterol relative to the protein moiety, apolipoprotein B. In HDL the components changed by the same percentage, which indicates that in these women the ratio between HDL_2 and HDL_3 remained constant.

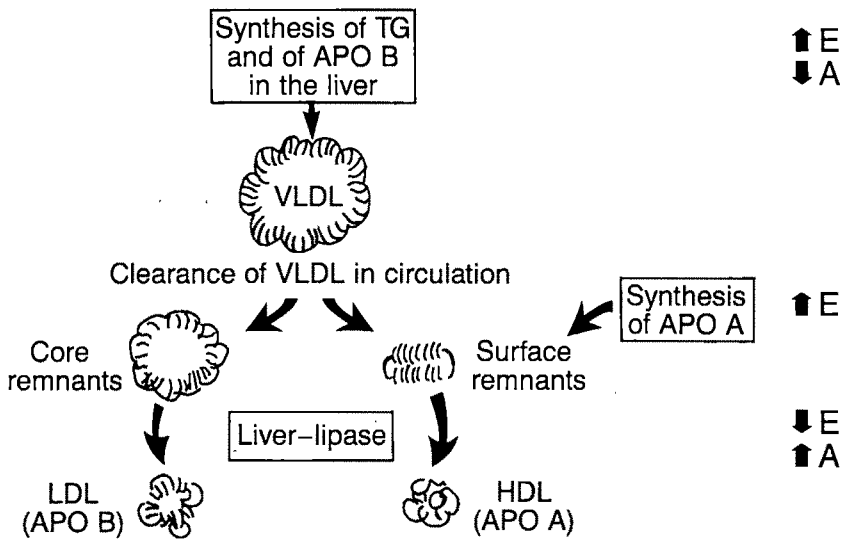

Fig. 2. Effect of estrogens *(E)* or antiestrogens/androgens *(A)* on lipoprotein metabolism: a simplified scheme. Triglyceride *(TG)* synthesis in the liver is enhanced by E and inhibited by A. Production of VLDL and its apolipoprotein B *(apoB)* follows that of TG. During intravascular delipidation of VLDL, remnants appear in the circulation. Remnants of the core are converted into LDL by liver lipolytic activity *(LLA)* of liver lipase; surface remnants take up apolipoprotein A *(apo A)*. Synthesis of apoA is enhanced by E. Resulting particles are converted into HDL_2 and subsequently (by LLA) into HDL_3. LLA is inhibited by E and enhanced by A. For the effects of oral contraceptives, see text.

Comment

The effect of GTD-EE and DSG-EE on lipoprotein metabolism was apparently similar. The changes were in agreement with earlier studies performed by us[15] and others.[19] The consequence of these findings on cardiovascular risk is unknown, but on the basis of current knowledge, it seems unlikely that the induced changes increase the risk. Serum levels of the two lipoproteins possibly involved in atherogenesis remained within normal limits. If the epidemiologic findings of apolipoproteins A_1[5] and B[2] in relating to the incidence of coronary heart disease can be applied to these data in women (the former negatively and the latter positively correlated with the incidence in men), then the increase in risk by the rise in apolipoprotein B should be offset by the decrease in risk resulting from the rise in apolipoproteins A_1 and A_2.[20] The rise in triglyceride level is probably of very little relevance[21] for risk, if at all.

The mechanism of the estrogenic/androgenic effect on lipoprotein levels is only partly understood. Estrogens enhance both the triglyceride synthesis rate in the liver[22-24] and subsequently that of very low–density lipoprotein (VLDL). This explains the rise in serum triglyceride levels. It may be postulated that the rate of synthesis of the main carrier apolipoprotein of VLDL, apolipoprotein B, is also increased.[25] As VLDL is converted to LDL in the circulation, the rise in LDL apolipoprotein B levels may be explained as a consequence of its increased formation (i.e., an estogenic effect). It should be noted that the technique of measuring apolipoprotein B applied in this work excludes VLDL apolipoprotein B and only allows the LDL apolipoprotein B to penetrate the radial immunodiffusion gel.[18]

The increase in HDL levels may be explained partly by the enhancement of apolipoprotein A_1 synthesis by estrogens.[25] On the other hand, clearance of HDL may be hampered because liver lipase activity is probably inhibited by the estrogenic effect[26] of both preparations (Fig. 2).

In LDL the increase in apolipoprotein B relative to LDL cholesterol caused a lowering of the ratio of LDL cholesterol/apolipoprotein B. This can also be explained by assuming that the liver lipase activity (Fig. 2) is inhibited[15, 26] during OC use. Thus the conversion of core remnants of VLDL to LDL may be reduced, resulting in an accumulation of LDL precursors and cholesterol-poor/triglyceride-rich LDL particles as found in congenital liver lipase activity deficiency.[27] An alternative hypothesis is that the enhancement of VLDL production[22-24] by the estrogenic effect of OC caused an increase in apolipoprotein B turnover and apolipoprotein B levels, whereas in the circulation the filling of the particles with cholesterol ester[28] lagged behind.

In HDL no change in composition was found, which suggests that the ratio between the two subfractions HDL_2 and HDL_3 remained constant. Thus the expected

liver lipase activity inhibition, if any, apparently failed to cause accumulation of HDL_2 (Fig. 2).

In conclusion the low-dose OC preparations studied here and earlier[15] show evidence of an estrogenic dominance in their effect on lipoprotein lipid and apolipoprotein levels. After six cycles, LDL apolipoprotein B still significantly increases, which indicates that the (V)LDL transport reaches a new set point after only 12 cycles. Thus studies on the ultimate effect of OC on lipoprotein metabolism require at least 1 year.

During low-dose OC use, lipoprotein levels in most patients remain within desirable limits. The two OCs studied do not differ in the degree of changes brought about in these levels. The impact of these changes on the risk of atherogenesis is probably minor, if at all.

We thank Miss E. de Wit and Mr. H. A. van der Voort and Miss H. Th. A. de Pagter for excellent technical assistance.

Time-dependent alterations in lipid metabolism during treatment with low-dose oral contraceptives

Herbert Kuhl, PhD, Winfried März, Claudia Jung-Hoffmann, MD, Frauke Heidt, and Werner Gross, MD

Frankfurt am Main, Federal Republic of Germany

The effect of sex steroids on lipid metabolism depends on the type and dose of the compounds, the route of administration, and the duration of treatment. Therefore the composition of an oral contraceptive determines the resultant effect on lipids and lipoproteins. During 12 months of treatment, the effects of two oral contraceptives containing 30 μg of ethinyl estradiol and 150 μg of desogestrel (EE/DG) or 75 μg of gestodene (EE/GSD) on 19 serum parameters of lipid metabolism were followed in 11 women each. There was no change in total cholesterol and phospholipids. Total triglyceride levels were significantly elevated only by EE/GSD. After 3 and 6 months of intake of both preparations, a transitory increase in the triglyceride content of very low–density lipoprotein and low-density lipoprotein and a decrease in low-density lipoprotein–phospholipids was observed. After 12 months, very low–density lipoprotein cholesterol, very low–density lipoprotein phospholipids, and apolipoprotein B were significantly elevated, whereas very low–density lipoprotein triglycerides and all components of low-density lipoprotein were unchanged. Most of the components of high-density lipoprotein (HDL) were increased as a result of a rise in HDL_3 and apolipoprotein A_2, whereas HDL_2 and apolipoprotein A_1 were not altered. There was no significant difference between the effects of the two preparations, although those of EE/GSD were mostly more pronounced. The increase in high-density lipoprotein, very low–density lipoprotein, and total triglycerides reflects a slight preponderance of the effect of the estrogen component. Because low-density lipoprotein cholesterol and total cholesterol were not changed, treatment with both formulations is in all probability not associated with an elevated risk of atherosclerosis. (Am J Obstet Gynecol 1990;163:363-9.)

Key words: Low-dose oral contraceptives, desogestrel, gestodene, ethinyl estradiol, lipids, lipoproteins

A series of investigations has demonstrated that sex steroids may influence lipid metabolism. The changes in lipid levels and the composition of lipoproteins are dependent on the type and dose of the compounds, the route of administration, and the duration of treatment.[1-5] With respect to steroid dose and the route of administration, it must be emphasized that the steroid concentration circulating through the liver determines the effect. Although transdermal estrogen replacement therapy is regarded as ineffective, it has been shown that percutaneous and subcutaneous treatment with high doses of estradiol, resulting in estradiol levels of more than 200 pg/ml, increases high-density lipoprotein cholesterol and reduces low-density lipoprotein cholesterol similar to oral treatment with low-dose estradiol.[6,7]

The changes in lipid parameters mainly reflect the hepatic effects of sex steroids. Estrogens stimulate the production of triglycerides, very low–density lipoprotein, HDL_3, and apolipoproteins A_1, A_2, and B in the liver,[8-10] enhance the synthesis of hepatic B:E and E receptors, which are important for the clearance of intermediate-density lipoprotein, low-density lipoprotein, and chylomicron remnants,[11-13] inhibit hepatic triglyceride lipase, which degrades the triglycerides and phospholipids of HDL_2,[14] and increase the lecithin content of phospholipids.[15,16] Most of these effects are antagonized by progestogens, particularly by nortestosterone derivatives, on account of their antiestrogenic or androgenic properties. Progestogens inhibit the hepatic production of triglycerides, very-low–density lipoprotein, and apolipoprotein A_1, stimulate the activity of hepatic triglyceride lipase, and decrease the lecithin content of phospholipids.[16-18]

Therefore the composition of the pill is responsible for the resultant effect on lipids and lipoproteins. The higher the dose of ethinyl estradiol, the higher are the levels of total triglycerides, whereas the progestogen component exerts only a modulatory effect. The type and dose of the progestogen, however, determines the effect on low-density lipoprotein cholesterol, which is supposed to be a risk factor for the development of atherosclerosis. Levonorgestrel increases this lipopro-

tein fraction more than norethisterone, whereas ethynodiol diacetate has a minor effect (Table I).[1, 3, 4] On the other hand, the higher the dose of levonorgestrel, the more pronounced is the reduction in high-density lipoprotein cholesterol, whereas preparations containing norethisterone or ethynodiol diacetate have nearly no effect.

However, it is possible to counterbalance this adverse effect of levonorgestrel on lipid metabolism by a proper composition of the pill. Triphasic formulations containing ethinyl estradiol and levonorgestrel have been shown not to decrease high-density lipoprotein cholesterol and not to increase low-density lipoprotein cholesterol; the effects on various serum parameters of lipid metabolism even indicate a slight overweigh of the estrogen component (Table II).[19]

The introduction of the new progestogens, desogestrel, norgestimate, and gestodene, with high progestogenic but relatively low androgenic activities, rendered it possible to reduce the ethinyl estradiol dose of monophasic pills to 30 μg or less without an adverse change in the lipoprotein pattern. The present study considered the effects of two low-dose oral contraceptives containing 30 μg of ethinyl estradiol and 150 μg of desogestrel (EE/DG) or 75 μg of gestodene (EE/GSD) on 19 serum parameters of lipid metabolism during 12 months of treatment.

Material and methods

Twenty-two normal healthy volunteers with regular menstrual cycles who were between 18 and 35 years old participated in the study. Informed consent was obtained. The women had not used hormonal contraceptives for at least 3 months before the study and were not under interfering pharmacologic therapy. An internal and gynecologic examination, including a Papanicolaou smear, was carried out before subject selection. During a control cycle, ovulation was confirmed to have probably taken place by the determination of serum progesterone (>3 ng/ml).

Two groups of 11 women each were randomly assigned to take preparation containing 30 μg of ethinyl estradiol and 75 μg of gestodene (Schering AG, Berlin, Federal Republic of Germany) or that containing 30 μg of ethinyl estradiol and 150 μg of desogestrel (Organon GmbH, Oberschleissheim, Federal Republic of Germany) for 12 months.

Blood samples were taken by venipuncture after overnight fasting between 8:00 and 10:00 AM (i.e., 24 hours after first pill intake) on days 1, 10, and 21 of the first, third, sixth, and twelfth treatment cycle and of the control cycle preceding the first treatment cycle. Each sample was drawn into tubes containing ethylenediaminetetraacetic acid · K_2 (1.5 to 2 mg/ml). Plasma was prepared by low-speed centrifugation

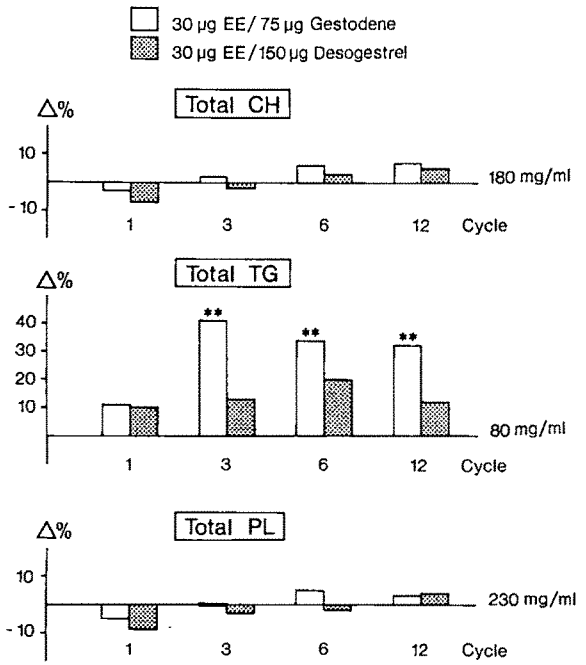

Fig. 1. Average changes (%) in the serum levels of total cholesterol *(CH)*, triglycerides *(TG)*, and phospholipids *(PL)* during 12 months of treatment with EE/GSD or EE/DG. Average control values are given at the end of the abscissa. ** $p < 0.01$ versus controls.

(1500 × *g*, 30 minutes) and kept at 4° C during storage. All determinations of lipoproteins were completed within 1 week after blood collection.

Cholesterol (CHOD-PAP-Method), triglycerides (GPO-PAP), and phospholipids were determined using reagents from Boehringer (Mannheim, Federal Republic of Germany). Very low–density lipoproteins were quantified in their lipid constituents after preparative ultracentrifugation at d < 1.00 gm kg/L.[20] High-density lipoproteins were determined after phosphotungstate/$MgCl_2$ precipitation of apolipoprotein B–containing lipoproteins, and high-density lipoprotein subfractions HDL_2 and HDL_3 were resolved by ultracentrifugation in the respective supernatants at d = 1.125 kg/L as previously described.[21] Low-density lipoproteins were calculated as differences between total lipids and high-density lipoprotein + very low–density lipoprotein. Apolipoproteins A_1 and A_2 were quantified by zone immunoelectrophoresis,[22] and apolipoprotein B was measured by conventional radialimmunodiffusion with NOR partigen plates (Behringwerke AG, Marburg, Federal Republic of Germany).

Data were analyzed by multivariate analysis of variance (repeated measures design) for the comparison of EE/DG versus EE/GSD or by the Student paired *t* test for the comparison of treatment cycles versus control cycles or of different treatment cycles.

Results

The determination of lipids and lipoprotein components, which was carried out three times during the control cycle and 12 times during the year of treatment in each of 22 volunteers, revealed great intra- and interindividual variations. Therefore no significant difference between the effects of both oral contraceptives on lipid metabolism could be found.

The changes observed in some parameters during treatment were to a certain degree dependent on time. In most cases there was no effect during the first treatment cycle, whereas during the following cycles various significant alterations became discernible compared with the control cycle. On the other hand, some significant changes that occurred during the first treatment cycle disappeared during the following treatment period.

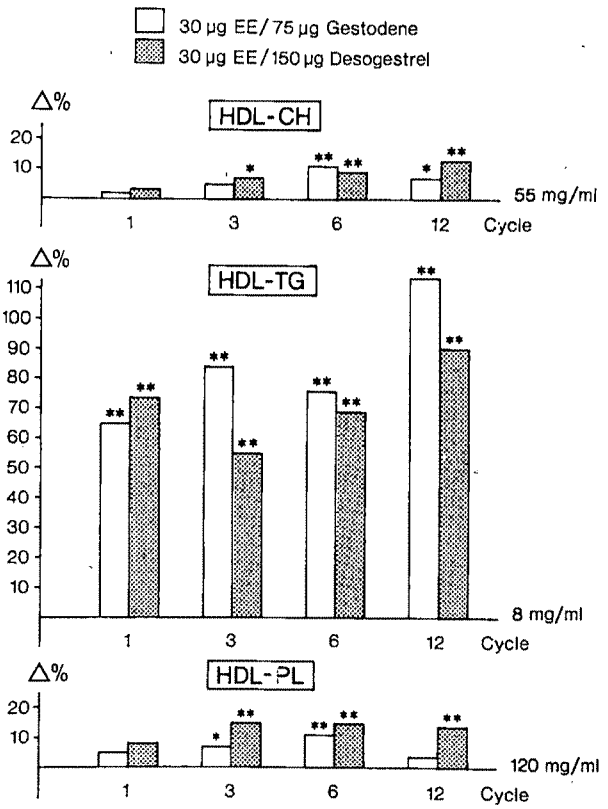

Fig. 4. Average changes (%) in the serum levels of high-density lipoprotein cholesterol *(HDL-CH)*, high-density lipoprotein triglycerides *(HDL-TG)*, and high-density lipoprotein phospholipids *(HDL-PL)* during 12 months of treatment with EE/GSD or EE/DG. Average control values are given at the end of the abscissa. * $p < 0.05$; ** $p < 0.01$ versus controls.

There was no influence of both preparations on total cholesterol and phospholipids, whereas total triglycerides were considerably elevated with EE/GSD ($p < 0.01$) and moderately but not significantly with EE/DG (Fig. 1).

The cholesterol content of very low–density lipoprotein was increased after 6 and 12 months; the effect was more pronounced during treatment with EE/GSD. There was also a significant increase in very low–density lipoprotein phospholipids and in apolipoprotein B, wheres that of very low–density lipoprotein triglycerides was only transitory (Fig. 2).

Low-density lipoprotein cholesterol and low-density lipoprotein phospholipids were significantly decreased during the first treatment cycle, but thereafter the effect extenuated and disappeared after 12 months of treatment. The increase in low-density lipoprotein triglycerides during the third and sixth month of intake of EE/GSD was also only transitory (Fig. 3).

There was a significant increase in the cholesterol, triglyceride, and phospholipid content of high-density lipoprotein and in the level of apolipoprotein A_2 during intake of both formulations, which was mainly because of an increase in HDL_3 (Figs. 4 and 5). Contrary to this, there was no change in HDL_2 and apolipoprotein A_1 except a transitory elevation in HDL_2 cholesterol and phospholipids during the first month of intake of EE/GSD (Fig. 6).

Comment

The present study demonstrates an increase in total triglycerides, very low–density lipoproteins, and apolipoprotein B, indicating an overweigh of the effects of the estrogen component on lipid metabolism because estrogens have been shown to stimulate very low–density lipoprotein synthesis and secretion.[23] The effects were considerably more pronounced during treatment with EE/GSD, although the differences compared with those of EE/GD are not significant as a result of the great intra/interindividual variations. A similar elevation in the triglyceride levels of 20% to 40%,[24-31] of 25% to 55% in the very low–density lipoprotein components,[25] and of 20% to 40%[27, 32] in the apolipoprotein B concentrations during treatment with EE/DG has previously been reported, even though several investigators did not observe a change in very low–density lipoprotein or apolipoprotein B.[27, 30, 31]

Most of these studies that had been carried out for 6 months confirm our findings that treatment with

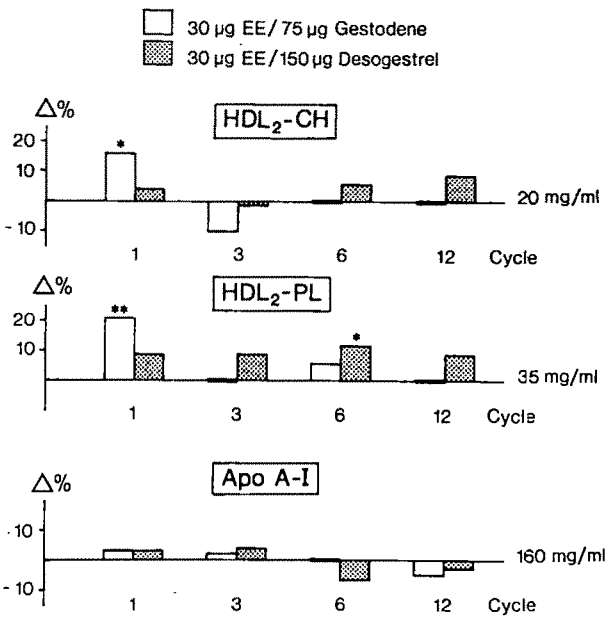

Fig. 6. Average changes (%) in the serum levels of HDL_2 cholesterol, HDL_2 phospholipids, and apolipoprotein A_1 during 12 months of treatment with EE/GSD or EE/DG. Average control values are given at the end of the abscissa. * $p < 0.05$; ** $p < 0.01$ versus controls.

EE/DG has no influence on low-density lipoprotein levels.[24, 25, 27, 28, 32] The significant rise in low-density lipoprotein after 3 and 6 months of intake of EE/GSD and the decrease in low-density lipoprotein phospholipids with both preparations was only transitory and disappeared after 12 months. This indicates an influence of the duration of treatment, reflecting a type of adaptation of some metabolic steps. A time-dependent change in the lipoprotein pattern during intake of a low dose ethinyl estradiol–containing and levonorgestrel-containing oral contraceptive has previously been reported.[33] However, the maintenance of elevated triglycerides, very low–density lipoprotein, and apolipoprotein B levels demonstrates that the stimulation of hepatic synthesis of these parameters continues during 12 months of treatment. Because of the enhanced secretion of very low–density lipoprotein, the enhanced hydrolyzation of very low–density lipoprotein triglycerides by the lipoprotein lipase in muscle and fat tissue leads to an increased formation of low-density lipoprotein by way of intermediate-density lipoprotein. In the present study, low-density lipoprotein levels remain unchanged, indicating that increased formation might be counterbalanced by enhanced clearance of intermediate-density lipoprotein in the liver. The cholesterol/triglyceride ratio was elevated in the very low–density lipoprotein fraction and decreased in the low-density lipoprotein fraction. This could be interpreted as reflecting a rise in the levels of intermediate-density lipoprotein and remnants, which are assumed to play a role in the development of atherosclerosis. Contrary to this, the increase in hepatic B:E and E receptors allows enhanced removal of intermediate-density lipoprotein, low-density lipoprotein, and remnants from the circulation.[11-13] Moreover, there is no evidence that long-term intake of oral contraceptives promotes the development of atherosclerosis.

The preponderance of the effect of the estrogen component in both preparations is also reflected by the increase in high-density lipoprotein, because progestogens with their pronounced androgenic activity decrease serum high-density lipoprotein cholesterol in a dose-dependent manner.[34] Treatment with both EE/DG and EE/GSD resulted in a small but significant rise in nearly all components of high-density lipoprotein. The effect was based on a rise in HDL_3 and apolipoprotein A_2, which is mainly contained in HDL_3, whereas HDL_2 and apolipoprotein A_1 were not altered. An increase in HDL_3 but not in HDL_2 during intake of EE/DG has also been previously observed.[27, 31, 32] Contrary to this, our results of apolipoprotein A_1 do not agree with those of several studies, which showed an increase of 20% to 30%.[27-32]

The rise in HDL_3 and apolipoprotein A_2 levels is probably caused by an enhanced hepatic synthesis stimulated by ethinyl estradiol, whereas progestogens seem to be ineffective.[35, 36] On the other hand, progestogens may counteract ethinyl estradiol–stimulated apolipoprotein A_1 production.[33] Because of the elevated supply

with the substrate, an enhanced peripheral lipolysis of very low–density lipoprotein leads to an increased conversion of HDL_3 to HDL_2 through assimilation of cholesterol, phospholipids, and apolipoproteins from triglyceride-rich particles.[37] Because HDL_2 levels remained unchanged, this might be compensated by an enhanced degradation by hepatic triglyceride lipase. It has been demonstrated that treatment of postmenopausal women with desogestrel does not influence enzyme activity,[18] but it cannot be excluded that desogestrel and gestodene may abolish the inhibitory effect of ethinyl estradiol on the hepatic triglyceride lipase. HDL_2 had been shown to be the major substrate of the hepatic lipase, whereas very low–density lipoprotein triglyceride is hydrolyzed to a much lesser extent.[14] However, the enzyme may also play a role in the catabolism of smaller triglyceride-rich lipoproteins along the very low–density–intermediate-density–low-density lipoprotein pathway.[30]

The results clearly show that the risk of developing atherosclerosis, as far as the lipoprotein pattern is concerned, is not elevated during treatment with the two low-dose preparations. Rather, the slight increase in most of the high-density lipoprotein components and probably enhanced removal of atherogenic intermediate-density lipoprotein and remnants indicate a beneficial effect. It should be remembered that high-density lipoprotein stimulates not only reverse cholesterol transport but also inhibits smooth muscle cell proliferation, stimulates endothelial cell prostacyclin biosynthesis, facilitates the catabolism of triglyceride-rich lipoproteins, and possibly facilitates fibrinolysis.[39]

Effects of three combined oral contraceptive preparations containing desogestrel plus ethinyl estradiol on lipid metabolism in comparison with two levonorgestrel preparations

Helenius J. Kloosterboer, PhD, and Hans Rekers, MD
Oss, The Netherlands

The effects of three different desogestrel-containing combined oral contraceptive preparations on lipid metabolism were compared with those of two levonorgestrel preparations. The following preparations were studied: (1) monophasic desogestrel (150/30), (2) monophasic desogestrel (150/20, containing 20 μg of ethinyl estradiol instead of 30 μg of ethinyl estradiol, (3) biphasic desogestrel, (4) monophasic levonorgestrel (150/30), and (5) triphasic levonorgestrel. The effects of these preparations were assessed on high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, apolipoprotein A-I, apolipoprotein B, the ratio of high-density lipoprotein cholesterol to low-density lipoprotein cholesterol, and the ratio of apolipoprotein A-I to apolipoprotein B after 3 months of treatment, and the percentage changes with regard to pretreatment were calculated. The monophasic desogestrel (150/30) and biphasic desogestrel preparations induced higher high-density lipoprotein cholesterol and apolipoprotein A-I levels than did their levonorgestrel-containing counterparts. Low-density lipoprotein cholesterol levels were increased in monophasic levonorgestrel and clearly decreased in the lowest ethinyl estradiol–containing monophasic desogestrel (150/20) and biphasic desogestrel preparations. Apolipoprotein B increased in all preparations. The antiatherogenic indexes (ratios of high-density lipoprotein cholesterol to low-density lipoprotein cholesterol and apolipoprotein A-I to apolipoprotein B were higher for monophasic desogestrel (150/30) and biphasic desogestrel than for comparable levonorgestrel-containing preparations. The differences seen between the desogestrel and levonorgestrel preparations can best be explained by the lower intrinsic androgenicity of 3-keto-desogestrel (active metabolite of desogestrel) than that of levonorgestrel. (Am J Obstet Gynecol 1990;163:370-3.)

Key words: Desogestrel, lipid metabolism, oral contraceptives

The two constituents of combined oral contraceptives have counteracting effects on various lipid parameters. Ethinyl estradiol increases triglycerides, high-density lipoprotein cholesterol, and its major apolipoprotein, whereas low-density lipoprotein cholesterol is decreased. Progestogens, especially those derived from nortestosterone, have opposite effects on these parameters. Larsson-Cohn et al.[1] showed that for levonorgestrel-containing preparations, the ratio ethinyl estradiol to levonorgestrel determines the final effect on various lipid parameters.

In 1981 an oral contraceptive preparation containing the new progestogen, desogestrel (150 μg), in combination with 30 μg of ethinyl estradiol, was introduced. In comparative studies[2,3] it appeared that this oral contraceptive preparation induces a higher high-density lipoprotein cholesterol level than a similar combination of levonorgestrel and ethinyl estradiol. This difference is attributed to the less intrinsic androgenicity of 3-keto-desogestrel (the active metabolite of desogestrel) compared with that of levonorgestrel.[4] Another oral contraceptive preparation containing 150 μg of the progestogen, desogestrel, in combination with only 20 μg of ethinyl estradiol, was marketed in 1988. Furthermore, a biphasic preparation containing approximately

Table I. Composition and regimen of the oral contraceptive preparations used in the present study

Preparation		*Regimen*
Biphasic desogestrel	7 days	25 μg DSG + 40 μg EE
	14 days	125 μg DSG + 30 μg EE
Monophasic desogestrel (150/30)	21 days	150 μg DSG + 30 μg EE
Monophasic desogestrel (150/20)	21 days	150 μg DSG + 20 μg EE
Monophasic levonorgestrel	21 days	150 μg LNG + 30 μg EE
Triphasic levonorgestrel	6 days	50 μG LNG + 30 μg EE
	5 days	75 μg LNG + 40 μg EE
	10 days	125 μg LNG + 30 μg EE

30% less desogestrel than that in the monophasic preparations is in development. In past years several well-controlled studies were performed with these preparations, in which levonorgestrel preparations were used as reference to assess the effects on lipid metabolism. In this article we give a survey of our findings to see whether we can observe certain trends in effects on lipid metabolism in relation to the composition of the various preparations. We discuss the effects of the three desogestrel-containing preparations on some important lipid parameters (high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, apolipoprotein A-I, apolipoprotein B, and the ratios high-density lipoprotein cholesterol to low-density lipoprotein cholesterol and apolipoprotein A-I to apolipoprotein B) in comparison with those of monophasic and triphasic levonorgestrel preparations.

Material and methods

All women participating in the various studies were in good general health and without contraindications for oral contraceptives. They were 20 to 36 years of age with regular menstrual cycles and had no hormonal treatment 2 months before the start of the study. During the study, they did not receive any medication and were not allowed to change their life-style with respect to alcohol consumption, exercise, and smoking. Table I shows the composition of the oral contraceptives used and the intake regimen given.

Blood samples were taken after overnight fasting before the start of treatment and in the third treatment cycle on one of the last 3 days of tablet intake. Blood was collected in tubes containing ethylenediaminetetraacetic acid as anticoagulant and plasma was prepared according to a routine laboratory procedure. Serum was also prepared. All lipid assessments were carried out as previously described.[5]

Results

The effects of the various preparations on high-density lipoprotein cholesterol are illustrated in Fig. 1. A clear decrease in high-density lipoprotein cholesterol is observed with monophasic levonorgestrel. A reduction in the amount of levonorgestrel of approximately 30% as in triphasic levonorgestrel gives a smaller decrease in high-density lipoprotein cholesterol. The use of desogestrel as progestogen in two monophasic preparations gives a slight increase in high-density lipoprotein. Reducing the amount of desogestrel as in the biphasic preparation shows a further increase in high-density lipoprotein cholesterol. The apolipoprotein A-I levels increase for all preparations studied as seen in Fig. 2. We measured total apolipoprotein A-I levels in these studies, and because a small contribution of apolipoprotein A-I may be derived from serum fractions other than high-density lipoprotein, no decrease was observed for any of the preparations studied. Most likely the contribution to apolipoprotein A-I of these fractions is more or less similar for the various preparations, since the same trend is seen for apolipoprotein A-I as for high-density lipoprotein cholesterol.

The changes in low-density lipoprotein cholesterol are seen in Fig. 3. An increase in this atherogenic parameter is found for monophasic levonorgestrel, whereas no change is observed for the monophasic desogestrel (150/30) preparation. Surprisingly, the other monophasic desogestrel (150/20) shows a decrease. The increase in low-density lipoprotein cholesterol is less pronounced for triphasic levonorgestrel than for monophasic levonorgestrel, but its desogestrel-containing counterpart shows a clear decrease.

The apolipoprotein B levels measured in serum were increased for all preparations and did not show the trend found for low-density lipoprotein cholesterol (results not shown). The antiatherogenic indexes, ratio of high-density lipoprotein cholesterol to low-density lipoprotein cholesterol, and ratio of apolipoprotein A-I to apolipoprotein B were calculated, because various investigators believe that these parameters are the best indicators of cardiovascular risk. Both parameters

(Figs. 4 and 5) give the same pattern: a clear decrease in values for monophasic levonorgestrel, whereas the values for biphasic desogestrel show a profound increase.

Comment

The best explanation for the difference in effects on high-density lipoprotein between desogestrel preparations and comparable levonorgestrel preparations can be found in the lower intrinsic androgenicity of 3-keto-desogestrel compared with that of levonorgestrel.

Table II[4] shows the relative binding affinities for the progesterone and androgen receptors of the two progestogens. The calculated selectivity index for 3-keto-desogestrel is far higher than that of levonorgestrel.

Kuusi et al.[6] showed that the two progestogens, desogestrel and levonorgestrel, have a different effect on hepatic lipase. This enzyme is involved in the catabolism of HDL_2 and it is stimulated by levonorgestrel. Consequently, lower high-density lipoprotein cholesterol and apolipoprotein A-I, the major apolipoprotein of high-density lipoprotein, will be found for the levonorgestrel preparations compared with the desogestrel preparations. The difference in intrinsic androgenicity of the two progestogens is likely to be responsible for the difference in effect on low-density lipoprotein cholesterol. Reducing the dose of levonorgestrel as in the triphasic preparation diminishes the effects on lipid metabolism, whereas lowering the dose of desogestrel as in the biphasic preparation further improves the effects on lipid metabolism. Thus both the type and dose of the progestogen are important for the final effect on lipid metabolism.

The lower androgenicity of 3-keto-desogestrel makes it possible to reduce the amount of ethinyl estradiol to 20 μg without substantially impairing the lipid profile. Castelli[7] showed that high levels of high-density lipoprotein and low low-density lipoprotein decrease the risk of coronary heart disease in women.

In light of these observations, it can be concluded that oral contraceptive preparations with a good lipid profile (high high-density lipoprotein and low low-density lipoprotein) have an advantage. Therefore the better antiatherogenic indexes found with the desogestrel prepartions compared with those for the levonorgestrel preparations can be considered beneficial.

Metabolic changes during treatment with two different progestogens

Hanne Refn, MD, Andreas Kjær, MD, Anne-Mette Lebech, MD, Birgit Borggaard, MD, Lars Schierup, MD, and Arne Bremmelgaard, MD

Copenhagen, Denmark

Two triphasic oral contraceptives containing the same amount of ethinyl estradiol in combination with gestodene or levonorgestrel were compared with respect to contraceptive effect, cycle control, and effects on lipid metabolism and coagulation. Serum concentrations of gestodene, levonorgestrel, ovarian and pituitary hormones, and sex hormone–binding globulin were measured. Thirty-three healthy women were randomized into two groups receiving either of the preparations. Before treatment and in the third and sixth cycles, blood sample were drawn in the morning while subjects were still in bed to obtain basal conditions. The contraceptive effect and cycle control were good with both preparations, and there were only a few minor side effects. Sex hormone–binding globulin was elevated twofold in the levonorgestrel group and threefold in the gestodene group. The gestodene concentration in serum varied more than the levonorgestrel concentration, but with correction for variations in sex hormone–binding globulin binding, less variability in gestodene and levonorgestrel concentrations were seen. High-density lipoprotein$_2$ cholesterol decreased in the levonorgestrel group but was unchanged in the gestodene group, whereas apolipoprotein A_1 increased in the gestodene group but not in the levonorgestrel group. Antithrombin III decreased in the gestodene group but was unchanged in levonorgestrel-treated women. Factor VII increased in both groups but more in the gestodene group. We conclude that gestodene has a positive influence on lipid metabolism, probably because of its lower androgenicity, and a slightly negative influence on coagultion. The latter, however, probably has no clinical relevance. (Am J Obstet Gynecol 1990;163:374-7.)

Key words: Oral contraceptives, lipid metabolism, blood coagulation

During the past 25 years, oral contraceptives (OCs) have been improved continuously with respect to decreasing the dose of total steroid content and the introduction of new progestogens in an attempt to minimize adverse effects and provide contraception safety. Several epidemiologic studies[1-3] have established a connection between OC use and an increased risk of cardiovascular and thromboembolic diseases. The changes in lipid metabolism and hemostatic parameters leading to these serious adverse effects are dependent on the dose and type of steroids, especially progestogens.

The aim of this longitudinal study performed under basal conditions was to compare the clinical effects and changes in endogenous hormones, lipid metabolism, and coagulation in two groups of women receiving either the new progestogens gestodene (GES) or levonorgestrel (LNG) in combination with the same amount of ethinyl estradiol (EE). The changes were correlated with serum concentrations of the progestogens.

Material and methods

Thirty-three women requesting OCs volunteered to participate in this study. The participants were 19 to 36 years old, with normal weight and blood pressure, healthy, and with regular menstrual cycles. None had used hormonal treatment or had been pregnant 3 months before the study. The women were randomized into two groups receiving a triphasic preparation of either GES or LNG in combination with the same amount of EE (Table I). OC intake started on the first day of menstruation and was of 21 days' duration, followed by 7 days of withdrawal.

Blood samples were drawn in the luteal phase of the cycle before treatment (values that served as controls) and during the third and sixth cycles of medication. Basic conditions were ensured by drawing blood samples 24 hours after the last dose of medication and after overnight fasting while women were still at home in bed. Blood samples were centrifuged, and serum was stored at −20° C until analyzed.

The concentration of hormones was measured by radioimmunoassay, and sex hormone–binding globulin (SHBG) was measured by an immunoradiometric assay. Triglyceride and cholesterol levels were measured by enzymatic methods, and the remaining lipids

Table I. Dosage regimen of the two oral contraceptives

Triphasic—gestodene		*Triphasic—levonorgestrel*	
Dose	*Days*	*Dose*	*Days*
50 μg gestodene-30 μg ethinylestradiol	1-6	50 μg levonorgestrel-30 μg ethinylestradiol	1-6

*$p < 0.001$ (treatment versus controls).

were measured by precipitation and electroimmunoassay.[4-6] Antithrombin III and factor VII were measured by function, and fibrinogen was measured by coagulometric.[7]

Results are presented as mean ± SEM and are statistically evaluated by analysis of variance, followed by Duncan's test for multiple comparisons, $p < 0.05$ was considered significant.

Results

Clinical. Of the 33 women who entered the study, all completed three treatment cycles and 29 completed six cycles.

Both OC preparations gave good cycle control with a bleeding duration of 2 to 7 days. No woman reported withdrawal bleeding, but two women in each group had completely irregular bleeding. Three women in the GES group and two in the LNG group had an episode of breakthrough bleeding or spotting.

Three women in the LNG group and two in the GES group reported an increase in body weight of 2 to 3 kg.

Laboratory. Table II presents the serum levels of the endogenic hormone response and SHBG. Progesterone was depressed below 9 nmol/L in both treatment groups. Serum levels of estradiol, luteinizing hormone, and follicle-stimulating hormone were depressed to or below early follicular phase levels; they were more pronounced during treatment with GES than with LNG. Serum levels of SHBG, the main carrier protein of GES and LNG,[8] increased twofold during treatment with EE + LNG and threefold during treatment with EE + GES ($p < 0.001$).

Individual serum levels of progestogens were measured. The GES concentration varied from 6.4 to 30.8 nmol/L in the third cycle and increased to values of 8.2 to 27.9 nmol/L in the sixth treatment cycle ($p < 0.05$). In the LNG group measured LNG concentrations were unchanged between the third and sixth cycles of treatment, with a variation from 6.6 to 12.6 and 4.4 to 16.0 nmol/L, respectively. After correction for variation in SHBG binding, the levels of the two hormones varied less. GES ranged from 5.0 to 15.0 and LNG ranged from 5.4 to 14.9 nmol/L.

As shown in Table III, high-density lipoprotein$_2$ (HDL_2) cholesterol decreased in the group receiving LNG ($p < 0.05$), with 36% and 19% after 3 and 6 treatment cycles. HDL_2 cholesterol was unchanged in GES-treated women. Apolipoprotein A_1 increased significantly during GES treatment ($p < 0.01$). The increase was greater after six treatment cycles. Serum levels of triglycerides, total cholesterol, low-density lipoprotein cholesterol and HDL_3 cholesterol, and apolipoprotein B were unaffected during both treatments.

The coagulation parameters, which showed changes during OC treatment, are shown in Table IV. Antithrombin III decreased in the GES group after 6 months ($p < 0.05$). No changes were seen in women

Table III. Lipids and lipoproteins before and during treatment

Parameter	Control cycle, Luteal phase	EE + LNG		EE + GES	
		Cycle 3	Cycle 6	Cycle 3	Cycle 6

*$p < 0.01$ (treatment versus control).

receiving LNG. Factor VII was elevated in both groups ($p < 0.01$), with a greater increase in the GES group. No changes in fibrinogen were seen.

Comment

Both preparations had good and similar contraceptive effects and cycle control. The incidence of irregular bleeding and spotting was low in both groups. This could be because of similar serum levels of progestogens found in both groups.

Both OC inhibited ovulation effectively as determined from the low progesterone levels. Despite the lower dose of GES compared with LNG, serum follicle-stimulating hormone and estradiol were lower in the GES group, which indicated that GES has a stronger progestogenic effect than did LNG. This is consistent with previous reports.[9] The rise in SHBG caused by EE appeared to be less counteracted by GES than by LNG. The two progestogens are strongly bound to SHBG (40% to 50%),[10] and this reduces the metabolic clearance rate and thereby raises the concentrations. The considerable interindividual variation in steady-state concentration reflected similar variations in SHBG levels, and therefore less variability in the biologically available fractions of LNG and GES was observed.

Changes in lipoprotein levels are associated with the incidence of cardiovascular disease. High levels of low-density lipoprotein and low levels of HDL cholesterol increase the risk of cardiovascular disease. The subfraction of HDL cholesterol, HDL_2 cholesterol, has a protective ability,[11, 12] along with the main carrier protein of HDL, apolipoprotein A_1. The finding that HDL_2 cholesterol was unchanged and that apolipoprotein A_1 increased in the GES group whereas HDL_2 cholesterol decreased in the LNG group speaks in favor of GES in respect to cardiovascular disease.

In general estrogens increase HDL cholesterol levels, and this effect is counteracted by progestogens, depending on their androgenicity.[13] Our study showed that GES had less androgen activity compared with LNG as reflected in SHBG levels.[14]

The natural anticoagulant, antithrombin III, decreased in the GES group. However, some authors emphasize that only significant changes (59%) are of any clinical relevance.[2] Factor VII of the "extrinsic pathway" increased in both groups, whereas fibrinogen was unchanged. The changes in the hemostatic system were small but were most pronounced in the GES group. Whether minor changes in coagulation parameters are of importance from a clinical point of view is doubtful.[15]

In conclusion we found that GES combined with EE in low-dose triphasic preparation, inhibited ovulation. Serum levels of GES showed greater variation than did LNG, but the unbound bioavailable fraction varied much less because of binding to SHBG, of which the concentration increased substantially. GES seemed to have a more favorable influence on lipid metabolism than did LNG, probably because of lower androgenicity, and GES affected coagulation factors slightly more than LNG, but the clinical importance is not obvious at the present time.

Effects of ethinyl estradiol combined with desogestrel and cyproterone acetate on glucose tolerance and insulin response to an oral glucose load: A one-year randomized, prospective, comparative trial

Bernard J. Jandrain, MD,[a] Dominique M. P. Humblet, MD,[b] Christiane B. Jaminet,[a] André J. Scheen, MD,[a] Ulysse J. Gaspard, MD, PhD,[b] and Pierre J. Lefebvre, MD, PhD[a]
Liège, Belgium

To investigate the effects of two slightly estrogen-dominant, monophasic, low-dose oral contraceptives on carbohydrate metabolism, 40 healthy young women were randomly allocated to receive either 30 μg of ethinyl estradiol + 150 μg of desogestrel, a 19-nortestosterone–derived progestin (Marvelon; $n = 21$) or 35 μg of ethinyl estradiol + 2 mg of cyproterone acetate, a 17-acetoxyprogesterone derivative (Diane-35; $n = (19)$ for a prospective observation period of 1 year. At baseline, 6, and 12 months, blood glucose, plasma insulin, and plasma C-peptide levels were measured during an oral glucose tolerance test. Although the changes were absent (Marvelon) or minimal (Diane-35) at 6 months, both groups had a slight increase in blood glucose levels at 12 months; overall glucose tolerance remaining, however, within the normal range. Plasma insulin levels remained unchanged in the Diane-35 group, which suggested increased insulin resistance, but were significantly decreased in the Marvelon group despite significant rises in plasma C–peptide levels. Comparison of plasma C-peptide and insulin changes suggests enhanced pancreatic insulin secretion and increased hepatic insulin metabolism with both Marvelon and Diane-35. (Am J Obstet Gynecol 1990;163:378-81.)

Key words: Carbohydrate metabolism, glucose tolerance, insulin metabolism, insulin secretion, oral contraceptives

Many studies have investigated the extent of the potential alterations in carbohydrate metabolism caused by different steroid types and dosages in combined oral contraceptives. It is now commonly accepted that low doses of estrogens, including ethinyl estradiol, have only very limited effects on glucose tolerance; thus the progestin compound appears to play the most important role.[1]

The aim of this study was to compare the potential effects on carbohydrate metabolism of two slightly estrogen-dominant monophasic oral contraceptive containing low-dose ethinyl estradiol plus either desogestrel (Marvelon) or cyproterone acetate (Diane-35). For that purpose, we designed a 1-year randomized, prospective study in normal women. In addition to glucose tolerance, we measured not only peripheral plasma insulin levels but also plasma C-peptide concentrations to assess pancreatic insulin secretion and insulin metabolism.

Subjects

The characteristics of the subjects investigated were quite comparable in both groups treated with either Marvelon or Diane (Table I). Forty healthy Belgian young women about 20 to 30 years of age, most of whom were medical students and nurses recruited from our University Hospital, participated. They had either never used oral contraceptives previously or discontinued use of oral contraceptives for at least 8 weeks before the study. In particular, none had a family history of diabetes, all were within 15% of their ideal body weight, and were nonsmokers. No differences in clinical characteristics, alcohol drinking habits, or physical exercise were demonstrable between the groups. They had none of the usual contraindications to oral contraceptive use. All subjects gave their free and informed consent, and the study was approved by the Ethical Committee for Human Investigations of the University of Liège.

Treatment

The subjects were randomly allocated for 12 months to receive either Marvelon ($n = 21$), 30 μg of ethinyl estradiol + 150 μg of desogestrel, a 19-nortestosterone (gonane) derivative with slight androgenic/antiestrogenic properties,[2] or Diane-35 ($n = 19$), 35 μg of eth-

inyl estradiol + 2 mg of cyproterone acetate, a 17-acetoxyprogesterone progestin with antiandrogenic activity.[3]

Experimental procedure

Carbohydrate metabolism was assessed by means of an oral glucose tolerance test (75 gm of glucose dissolved in 300 ml of water). This oral glucose tolerance test was performed after an overnight fast, during the last 7 days before presumed menstruation in a spontaneous cycle (baseline) and within the last 5 days of pill intake during the sixth and twelfth months of oral contraceptive use in each subject. To avoid potential circannual changes in endogenous insulin secretion in response to glucose loading, the 40 subjects were introduced into the study at different time intervals over a 9-month period.

Blood samples. Blood samples were collected through a flexible catheter inserted into a superficial forearm vein before and every 30 minutes for 3 hours after the ingestion of glucose. Blood glucose was determined by the hexokinase method, plasma immunoreactive insulin by a method derived from the C-method of Hales and Randle,[4] and plasma C-peptide by the radioimmunoassay method of Heding.[5] Samples for immunoreactive insulin and C-peptide were kept frozen until the end of the study period for each subject and run in duplicate in the same assay procedures, thereby minimizing interassay variability and multiple thawing of samples.

Calculations and statistical evaluation. For each group, the means and standard errors of the means for all parameters were calculated at each time of measurement. The areas under the curves from 0 to 180 minutes were then calculated by the trapezoidal method. Results are expressed as changes (±%) at six and 12 months from values obtained at baseline. The statistical evaluation was performed according to the Student t test for paired values.

Results

Diane-35 (Table II). Initial fasting blood glucose values were normal in all persons tested; however, a slight but significant increase was recorded at 12 months. Blood glucose levels recorded during the pretreatment oral glucose tolerance test (baseline) were within the normal range. During treatment, a trend to a moderate increase in area under the curve blood glucose was already observed at 6 months; this difference was significant at 12 months of therapy. However, no value of blood glucose level attained a pathological level, indicating impaired glucose tolerance. At 6 months, a tendency to increased fasting immunoreactive insulin values and area under the curve immunoreactive insulin was observed; however, the differences did not reach statistical significance mostly because of the interindividual fluctuations in plasma immunoreactive insulin levels and almost disappeared after 12 months of therapy. In contrast, fasting plasma C-peptide levels and area under the curve C-peptide were significantly increased throughout the treatment period, at 6 months, and even more at 12 months. Thus the C-peptide/immunoreactive insulin molar ratio measured in the fasting state tended to be slightly increased under Diane-

Table III. Changes in blood glucose, plasma insulin, plasma C-peptide, and C-peptide/immunoreactive insulin molar ratio under Marvelon ($n = 21$); results correspond to changes at 6 and 12 months from 0 month values (expressed in percent)

	T6 vs T0		*T12 vs T0*	
	Fasting values	$AUC_{0\text{-}180\ min}$	*Fasting values*	$AUC_{0\text{-}180\ min}$
Blood glucose	+1.6% (NS)	+7.4% (NS)	+5.7% (NS)	+13.9% ($p < 0.005$)
Plasma insulin	−9.1% (NS)	+0.7% (NS)	−27.3% ($p < 0.10$)	−21.1% ($p < 0.005$)
Plasma C-peptide	+1.9% (NS)	+4.6% (NS)	+13.0% ($p < 0.10$)	+19.3% ($p < 0.01$)
C-peptide/immunoreactive insulin	+36.4% (NS)	+12.4% (NS)	+86.9% ($p < 0.005$)	+54.2% ($p < 0.001$)

T6, 6 months; *T0*, baseline; *T12*, 12 months; *AUC*, area under the curve.

35; this increase was more marked when considering the molar ratio area under the curve C-peptide/area under the curve immunoreactive insulin and became highly significant after 12 months of therapy.

Marvelon (Table III). Fasting blood glucose levels and glucose tolerance assessed during the pretreatment oral glucose tolerance test (baseline) were strictly within the normal range. At 6 months, no significant differences were observed for blood glucose, plasma immunoreactive insulin, and C-peptide levels either in the fasting state or during the oral glucose tolerance test. At 12 months, a discrete, nonsignificant increase in fasting blood glucose levels was recorded, with a significant increase in the mean area under the curve blood glucose. However, here again, no subject met the criteria of impaired glucose tolerance. A tendency toward decreased fasting plasma immunoreactive insulin levels was observed with a significant reduction of the insulin response to the glucose load, as reflected by the lower area under the curve immunoreactive insulin. In contrast, fasting plasma C-peptide levels tended to increase, and area under the curve C-peptide showed a significant enhancement of insulin secretion. Thus although unchanged at 6 months, the C-peptide/immunoreactive insulin molar ratio, which was calculated in both basal and postglucose conditions, significantly increased at 12 months.

Comment

It has been known for a long time that oral contraceptive use may increase the risk of developing altered glucose tolerance[1]; impairment of glucose tolerance and hyperinsulinism, which indicates a state of insulin resistance, are involved in the occurrence of cardiovascular disease, hypertension, and non-insulin-dependent diabetes mellitus.[6,7]

Previous studies have shown that progestogens derived from 17-hydroxyprogesterone have a lower potential for impairing glucose tolerance and increasing insulin resistance than do the more potent 19-nortestosterone derivatives.[1]

In contrast, our study with Diane-35, containing a 17-acetoxyprogesterone derivative, clearly demonstrated a slight deterioration in glucose tolerance, which was significant after 12 months of use; however, no blood glucose value reached the degree of impaired glucose tolerance. This increase in blood glucose levels occurred without any decrease in plasma immunoreactive insulin levels; this suggests a mechanism of insulin resistance that is still poorly understood and could involve reduced levels of hepatic insulin receptors as well as postreceptor changes in intracellular glucose metabolism.[8] According to this latter hypothesis, a recent in vivo study with the euglycemic clamp technique has shown that oral contraceptive administration (30 μg of ethinyl estradiol + 150 μg of levonorgestrel) induced a significant reduction of the insulin-induced glucose disposal, suggesting peripheral (muscular) tissue insulin resistance.[9] Although plasma immunoreactive insulin levels remained almost unchanged throughout our study, we observed a highly significant increase in plasma C-peptide levels, suggesting increased pancreatic insulin secretion but enhanced insulin metabolism.

With Marvelon, two 6-month studies have reported a slight deterioration in glucose tolerance (increase in blood glucose levels) but with conflictual results on insulin response. The first study showed a statistically significant increase in plasma immunoreactive insulin levels, which suggests the development of insulin resistance,[10] whereas our study[11] demonstrated a decrease in insulin response. Our first interpretation was that this difference could be attributed to circannual changes in glucose-insulin homeostasis, as observed by Reinberg et al.[12] Accordingly we modified our subsequent protocol to avoid this interference, and here again we confirm the occurrence of a slight but significant decrease in plasma immunoreactive insulin levels, which was even more pronounced after 12 months of treatment. Because we recorded simultaneously an increase in plasma C-peptide levels, we can conclude that insulin secretion is stimulated, but that at the same time,

the metabolic clearance rate of insulin is enhanced. The interference of oral contraceptive agents with the liver metabolism is of common knowledge, and more than 50% of insulin is extracted by the liver. Thus we can suspect a possible interference at this hepatic level. Moreover, we have recently reported that the classic potentiation by obesity of the peripheral hyperinsulinism observed during an oral glucose tolerance test almost disappears during the last trimester of pregnancy.[13]

It would be interesting to carry out protocols studying carefully the metabolic clearance rate of insulin during oral contraceptive treatment. To the best of our knowledge, only one study has recently demonstrated that a combination oral contraceptive containing 30 μg of ethinyl estradiol + 150 μg of levonorgestrel did not significantly affect the metabolic clearance rate of insulin.[9] However, that study was performed after only 3 and 6 months of treatment, namely, a duration after which we did not find any significant changes in the C-peptide/immunoreactive insulin molar ratio in our study. Therefore more prolonged studies are needed before any definite conclusions can be drawn on this matter.

Effects of oral contraceptives on carbohydrate and lipid metabolisms in a healthy population: The Telecom Study

Dominique Simon, MD,[a, b] Colette Senan,[c] Philippe Garnier, MD,[d] Michel Saint-Paul, MD,[e] Edith Garat,[a] Nadine Thibult,[a] and Laure Papoz, PhD[a]

Villejuif Cedex, Créteil, Fresnes, and Paris, France

In a cross-sectional study that aimed to identify risk factors for diabetes, 1290 consecutive, healthy, nonpregnant women of child-bearing age were examined in a center for preventive medicine. An in-depth interview about menses, use of oral contraceptives, and menopause was performed. Plasma glucose at fasting and 2 hours after a 75 gm glucose load, glycated hemoglobin A_{1c}, fasting plasma insulin, total plasma cholesterol, and triglycerides were measured. Compared with nonusers taking no progestogens, oral contraceptive users (n = 431;33.4%) were younger ($p < 0.001$) and leaner ($p < 0.001$). After adjustment for age and body mass index, oral contraceptive users had higher 2-hour plasma glucose ($p < 0.001$), higher fasting plasma insulin ($p < 0.01$), and higher triglycerides levels ($p < 0.01$). Fasting plasma glucose, glycated hemoglobin A_{1c}, and total cholesterol did not significantly differ between the two groups. In relation to dosage and types of steroid components, few differences have been found between high-dose and low-dose oral contraceptives or according to the estrogen-progestogen balance of the preparations. Use of oral contraceptives appears to induce an increase of insulin-resistance markers, which have recently been cited as risk factors for ischemic vascular diseases. These markers should be carefully monitored in oral contraceptive users. (Am J Obstet Gynecol 1990;163:382-7.)

Key words: Oral contraceptives, high-dose/low-dose oral contraceptives, estrogen/progestogen balance, insulin resistance

Oral contraceptives are the most popular reversible method of contraception in the United States[1] and probably in all developed countries. Their low rate of failure, ranked second behind sterilization,[2] low cost, and acceptability will probably help keep consumption of oral contraceptives very high in the next decade worldwide. Thus there is a need to evaluate very carefully their side effects. Despite criticisms, which are mainly addressed at the observational nature of study designs used to investigate the relationship between oral contraceptives and cardiovascular diseases,[3] it is currently admitted that most of the epidemiologic surveys have indicated a link between oral contraceptive use and adverse cardiovascular events.[4-8] Oral contraceptives seem to generate these effects through deleterious changes in the coagulation process and in carbohydrate and lipid metabolisms.[9, 10] To reduce cardiovascular risk, a large-scale move toward preparations containing low doses of estrogens was initiated in the early 1970s, followed a few years later by efforts to minimize the dose of progestogens.[11, 12] Consequences of these changes in oral contraceptives prescription habits on carbohydrate and lipid metabolisms have been poorly evaluated as the ideal design—a prospective, comparative, randomized study of each new oral contraceptive[9] is difficult to realize because of obvious ethical and practical reasons. Moreover, the few surveys designed to address this issue have often been conducted on small samples and have led to contradictory conclusions.[13-21] Therefore this article assesses the influence of oral contraceptives on metabolic parameters in a large, healthy, female population and makes a comparison between oral contraceptive users and nonusers, and among users, according to estrogen dosage and estrogen/progestogen balance of the preparations.

Subjects and methods

From April 1985 to October 1987, 1290 consecutive, healthy women of child-bearing age, who voluntarily attended a center for preventive medicine, were examined in a cross-sectional study. Women who were pregnant, who had a self-reported history of diabetes, who were treated by progestogens alone, or who had hemoglobinopathies, were excluded. The subjects were "France-Telecom" employees working in the Paris area who are offered a medical check-up, free of charge,

Results show percentage or mean ± SEM as appropriate.

GGT, γ-Glutamyltransferase; *SHBG*, sex hormone–binding globulin.

**p* Value calculated after adjustment for age.

†Values adjusted for age and body mass index (calculated for age = 35 years and body mass index = 22.5 kg/m²).

‡Geometric mean with 95% confidence interval of mean in brackets when logarithmic transformation has been needed.

every 5 years for those under 40 years and every 2 years for those over 40 years.

A self-questionnaire, which was filled out at home, inquired about gynecologic and obstetric history, present oral contraceptive use with the brand name if any, regularity of menstrual cycle, and the first day of the last period. During the consultation, a secretary reviewed carefully all these data with the client and gave her a letter to be returned when her next menses began; 80% responded and indicated the date of the following menses.

Height, weight, and blood pressure were recorded at physical examination. The Quetelet index [weight(kg)/height(m)²] was used as a measure of body mass index. Fasting plasma glucose, plasma insulin (22), total cholesterol, triglycerides, and glycated hemoglobin A_{1c}[23] were measured and plasma glucose was also measured 2 hours after a 75 gm glucose load (2-hour plasma glucose).

Table I describes the study population and compares each nonmetabolic parameter between oral contraceptive users and nonusers. The sample consisted of around 87% whites and 12% blacks, mainly natives from the West Indies. Oral contraceptive users were significantly younger and leaner (Table I). After adjustment for age and body mass index, systolic and diastolic blood pressures were significantly higher in oral contraceptive users who also had significantly higher level of γ-glutamyltransferase and sex hormone–binding globulin (Table I).

Regarding metabolic parameters, comparisons have been made between oral contraceptive users and nonusers in a first step. Among users, subdivisions were then made according to dosage and types of steroid components. Thus by crossing estrogen content (high-dose/low-dose) with hormonal balance (estrogen/progestogen dominance), four subgroups of oral contraceptives have been identified (Table II), in which dosage of ethinyl estradiol, progestogen content, and number of users have been indicated for each oral contraceptive.

This classification of oral contraceptives led us to perform four comparisons in a second step: between high-dose and low-dose oral contraceptive users inside each hormone-dominance group and between estrogen-dominant and progestogen-dominant oral contraceptive users inside each estrogen-dose group. Statistical analysis used programs accessible through SAS[24] on a VAX 8530. The χ^2 tests and analysis of variance have been performed after logarithmic transformation when needed. When a significant difference has been observed for age or/and body mass index, comparisons for metabolic parameters have been adjusted for age or/and body mass index. For quantitative variables, the values reported are mean ± SEM or the mean followed by the 95% confidence interval for the mean when logarithmic transformation has been needed.

Results

Compared with the 859 oral contraceptive nonusers, the 431 oral contraceptive users were not significantly different for hemoglobin A_{1c}, fasting plasma glucose, and total cholesterol concentrations (Table III), but they had significantly higher 2-hour plasma glucose, higher fasting plasma insulin, and higher triglyceride levels as shown in Table III.

Within both the estrogen-dominant (Table IV) and the progestogen-dominant (Table V) oral contraceptive users, no significant difference has been observed according to the estrogen dose of oral contraceptives.

Table II. Oral contraceptives used

Among high-dose users, the estrogen-progestogen balance did not influence metabolic parameters (Table VI). On the contrary, when low-dose oral contraceptive users were considered, significant differences were found according to the estrogen-progestogen balance of the preparations (Table VII): users of progestogen-dominant, low-dose oral contraceptives were leaner ($p = 0.02$); after adjustment for body mass index, they had a marginally significant higher hemoglobin A_{1c} level (4.90% ± 0.03% vs 4.77% ± 0.07%; $p = 0.06$), with slighlty higher but nonsignificantly different plasma glucose values; their triglyceride level was significantly lower (71 mg/dl with 95% confidence interval = 68 to 74 mg/dl vs 78 mg/dl with 95% confidence
